A word as to the object of the preparation may not be out of place. It is well known that in the human economy the salivary glands and the pancreas secrete analogous principles, each having for its object the conversion of amylaceous principles into saccharine, that existing in the salivary secretion being known as ptyalin and that of the pancreatic juice as pancreatin. In the malted barley there is found a substance analogous to these, and having just as strong and subtle power of changing starch into sugar as the pepsin in the gastric secretion has the power of converting albuminous substances into peptone. This substance in malted barley is called diastase, and is formed during the process of germination or malting. A small portion of this substance has the power of converting an almost indefinite proportion of starch into sugar.

These facts being known, it is obvious that when the animal system is incapable, through deficiency of the natural secretions, of converting starch food into sugar, we must add some artificial saliva, as it were, to perform the work and make good the deficiency, and hence it is that the heavy feeling in the stomach observed after eating heartily of potatoes, corn-starch and other graminaceous or amylaceous food, is promptly removed by taking a small quantity of a good extract of malt.

Barley grown in high latitudes like Michigan, Canada, and the like, is generally the best, because of its containing more starch, which, in the process of mashing, is converted into sugar, and of course, there being more sugar the yield of extract is larger, thus making the operation more successful, pecuniarily, to the manufacturer.

The process of malting we need not describe, being familiar to us all, and for the purposes of the malt-making pharmacist may be practically ignored, it being better to purchase the malted barley of a professional maltster.

The barley, then, being properly malted, is ground coarsely, and a tub, preferably of cedar, with a false bottom perforated, and of a capacity of say 20 gallons (an old-fashioned upright churn answers very well), is filled with about 14 gallons of water, at a temperature of from 168° to 172° F. Into this tub about half a bushel of malt is added, little by little, until the whole is well stirred in. The tub is then well covered and set away in a warm room, and allowed to remain perfectly at rest for a period of three or four hours, taking care that the temperature does not fall below 150° F.

This is the process of mashing. At the expiration of the allotted time, the stop-cock below the perforated diaphragm is opened, and water of a temperature a little above the extract, which is now being drawn off below, and which we shall now call the wort, is sprinkled by means of a sieve or plant sprinkler, upon the top of the malt until the wort being drawn off below is almost tasteless or of so low a specific gravity that it will not pay the cost of evaporation. In large operations this sprinkling is done by means of a patented revolving instrument called a "sparge," and which much resembles a lawn-sprinkler, that revolves by the pressure of the water being ejected from each side in opposite directions, the water being supplied from a large tank in which it is heated by steam, and the exact temperature being easily controlled by valves commanding abundant supplies of both cold water and steam. This wort that we have drawn off from our mash-tub or percolator, we now place in the capsule or copper kettle, and evaporate by means of a water-bath to the required consistence; the first run should have a high specific gravity, and contain about a pound of malt sugar to the gallon of wort. We present samples of this evaporated wort, which is now our malt extract.

A word now regarding cleanliness. The mash-tub and all other wooden or metal utensils should be washed out at least once a week with dilute solution of caustic potash or soda, and any barrels, tubs, etc., should be kept filled with lime water when not in use, as the tendency of the wort which may be left in them is very great toward fermentation, and a few grains of malt accidentally left in the tub, and which have undergone putrefactive change, may completely spoil the subsequent batch of malt at the next mashing.

Extract of malt with iron is easily prepared by the addition of a syrupy solution of ferric pyrophosphate, in the proportion of four grains to the tablespoonful.

Extract of malt with pepsin has been proposed as a valuable preparation in dyspeptic troubles, since it would certainly have valuable digestive properties, acting upon both amylaceous and albuminous substances.

Extract of malt with cod liver oil is proposed as the acme of all emulsions of cod liver oil. When we reflect on the fact of cod liver oil being simply food and not medicine, and then combine this with a preparation having of itself the property of transforming non-assimilable food into that which may be easily assimilated, beside being a valuable nutrient, we have as an emulsion (and it makes a perfect emulsion without the use of any gum, sugar or other vehicle) a preparation of double the nutrient value of the ordinary emulsions of cod liver oil. A preparation, also, that is very pleasant to the palate as well as the stomach, a fact that, in these days of elegant pharmacy need not be overlooked.

The author exhibited a sample of the product and also an emulsion of cod-liver oil and extract of malt containing 50 per cent. of oil, its odour disguised with almond and wintergreen. It is readily prepared, no gum or other emulsifier being required. It readily mixes with water, but the oil separates as a creamy layer upon standing, and upon again shaking the mixture is restored.

Mr. A. P. Brown stated the same facts were true where an infusion of malt was used in this manner—the oil being emulsified by simply agitating it with the infusion.

Professor Remington exhibited specimens of Russian isinglass obtained from the Russian Commissioners. They comprise various kinds of sturgeon, carp and silure isinglass from Astrachan, consisting of leaves in various thicknesses, circular pieces and long cords tied together; also, so-called "crumbs."

Professor Maisch exhibited Dugong oil, also pure gelatin in sheets, made in Hanau, Germany, by Otto Lindenbauer, and a sample-card of coloured gelatin made by Carl Spatz. The raw material used is the residues from the bone-button works. The gelatin is of the finest quality—the samples exhibited, in addition to the white, were of many beautiful colours.

Parliamentary and Law Proceedings.

PAPERS PRESENTED TO PARLIAMENT.

INDIAN *versus* CHINESE OPIUM.

A blue book of commercial reports by Her Majesty's consuls in China, which has been recently issued, bears unmistakable evidence that the consumption of the native grown opium is largely increasing. In fact during last year its competition was so strong as to materially affect the quantity of Indian-grown opium imported at some of the Chinese ports. A most interesting report has been made by the Consul at Canton, Mr. B. Robertson of Canton, who says:—

"There is no doubt that the importation of Indian opium has not increased in the ratio that might have been expected. On the contrary, it has been stationary, whilst, on the other hand, the native production has so to a very large extent, showing that if the supply from India failed or was cut off entirely, its loss would in time be supplied from native sources. Some years since, Sir Rutherford Alcock, Her Majesty's Minister in China, called attention to the probability of the increase of native production, and the possibility of its superseding that of India. His remarks were received with doubt, but time has proved the soundness of his views, for the breadth of land under poppy cultivation has increased year by year, and the produce has unquestionably checked the increase of the Indian drug. The province of Szechuen is where it is chiefly grown, but in Shantung, Chili, Hupeh, etc., there is an increasing production, notwithstanding the occasional proclamations fulminated against it, and of which little notice is taken. It is a mistake, therefore, to suppose that the stoppage of the Indian supply would affect the consumption of opium in China. It might for a time cause some inconvenience to those who prefer it to the native product, but only for a time, for the habit of smoking the drug is so deeply seated as to have become a necessity with a very large section of the people, and the Government is wise enough not to interfere with it beyond the issue of warnings.

"While on this subject I think it well to quote from the Trade Report of the Port of Newchwang of 1874, furnished by Mr. Man, Commissioner of Customs there, some remarks of his upon native opium. He says:—

"'All over Sheng-king (another name for the province of Liao-tung, of which Newchwang is a port) the poppy may now be seen. Every town in the province is amply supplied from its yield. Mixed in a certain proportion with Indian, the use of the native drug is spreading among the gentry, while a resort to it pure gives the humblest peasant power of obtaining a longed-for and otherwise impossible luxury.

"'Passing northwards to Kirin, a province which has as yet but a thin and mixed population, and with great stretches of forest and mountain isolating, as it were, the light commanderies into which its government is subdivided, in the settled valleys of this territory, the colonization of which is now proceeding with rapid strides, of every ten mow of available soil, an average of eight is devoted to the poppy. An exodus of rather an extensive scale took place some months since of entire families from the lowlands of Liao-tung in the direction of the lately-occupied regions eastward of the lesser palisade. These people hardly made it any mystery that their object in thus seeking a new sphere was to turn to a golden profit the facilities there promised for an enterprise hampered by the nominal taboo at home.

"'Finally into Tsitsihar, a domain until recently scarcely visited by Europeans, ungauged as to capability, and where the hold of Government has ever been light, the advent of the banned plant has wrought a kind of revolution. Three or four years ago some emigrants from China, not having the fear of the law before their eyes, started this venture. Success resulted passing the wildest hopes; friends and relations poured in upon their track, and, notwithstanding a show at the start of great energy in repression, the number of communities obtaining a comfortable livelihood by this means has become so large, and the members thereof are, moreover, so rapidly increasing in wealth and power, that the military magistrates, even those most willing to enforce the law, dare not take measures which would certainly result in disturbance, and very possibly in defeat. Accepting, therefore, the apparently inevitable, and turning the illegality of the culture to a use not unknown to his civil colleagues in the mother-country, the marshal governor has practically enfranchised the trade by fixing a scale of extra fees on produce from the plantations over and above the one sole tax, the land assess, due to the imperial treasury. Speaking roughly, 12 taels per picul is the average exactment,* and it is willingly paid by the hardy settlers, who are shrewd enough to see and grasp the advantage such official recognition confers upon them. Without any interference on the part of their rulers, a growing population is thus allowed to continue in undisturbed possession of this fresh field of industry.

"'The increased demand for home-grown opium can no longer be attributed solely to the low and advantageous price at which it can be laid down. Successful efforts to improve the quality have begun to influence the results.'

"To these remarks of Mr. Man I may add some information obtained lately by me from native sources.

"Opium, which originally came from abroad, had towards the close of Ming dynasty (A.D. 1644), the name of 'Ya Fu-jung' (Cantonese, 'A-fu-yung;' Arabic, 'Afyun'). The 'Botanical Encyclopædia' also gives the name 'Afuyung.' At that time it was not known that the drug could be used for smoking purposes, but its properties were cooling and astringent, and it was used for diarrhœa and fevers, but with what admixture is not known. Subsequently it was made into paste and smoked, hence the present name of opium-smoking, which has also an astringent and antifebrile effect. It is relaxing and reduces the system.

"At first the only sort was Patna, followed afterwards by Malwa, then Benares, and finally Persian, all imported from abroad. Tradition describes Persian as hot and acrid, and liable to cause dysentery. It is all sent to the province of Kwangsi, as the chilly climate there is said to permit of its use.

"Kwantung (Canton) only consumes Patna and occasionally Malwa. Benares is used in the Prefectures of Hui-chow, Chao-chow (Swatow), and Kia-ying-chow, and is sent to other provinces of China. It is cheaper than the other kinds. Malwa is only used by one or two out of ten in Canton, and goes chiefly to the provinces.

"When China first began to cultivate the poppy it was called the 'Yung-su-hwa,' jar-shaped flower or capsule, and when the juice was extracted it was called white smoke or white tobacco. It is grown chiefly in Yünnan, where it covers the whole place; hence the name 'Yünnan white.' It is also grown on the hill-tops of Kansuh, but not to a tenth of the extent grown in Yünnan. It is exported from Yünnan to all the provinces, and is also smoked in Canton, being barely more than two-thirds the price of the foreign, but it is not so rich to the palate as Patna. Eight out of ten in the Prefecture of Canton, smoke Patna and the other two Yünnan. Other provinces use a great deal of Yünnan. Nearly every one in Hunàn, Hupeh, Yünnan, Kweichow, and Western Szechuen smoked Yünnan opium, and only the rich used Patna and Malwa, the reason being that, firstly, the price was cheaper; and secondly, it was easier to purchase than the prepared. Patna had to be bought by the ball and could not be purchased retail. Each ball was 4 lbs. in weight, and cost 8 dollars the catty ($1\frac{1}{3}$ lbs.), that is, 24 dollars the ball, whereas, the native could be bought by the ounce or the drachm if required. Again, native opium is much easier to prepare than foreign.

"Opium is divided by the Chinese into the following kinds or qualities:—

"*Foreign.*—1st termed 'Kung t'u' or Patna, $3\frac{1}{2}$ lbs. to the ball.

"2nd. 'Kung-tze-pai' or Malwa, about $3\frac{1}{3}$ lbs. to the packet of 5 or 3 inch cakes.

"3rd. 'Ku t'u,' or Benares, about $3\frac{1}{3}$ lbs. to the ball.

"4th. 'Chinta,' or golden opium, or Persian, made up like the second quality; this has a fiery flavour, and is little used by the Cantonese, as it causes dysentery.

"The above kinds are sent all over the Province of Kwangtung (Canton) and Kwangshi.

"*Native.*—Native opium is divided as follows:—

"1st. Called Yünnan pai or white opium, produced in the Province of Yünnan. It is made up into flat cakes.

"2nd. Syschuen Province also produces white opium, which comes only in small quantities.

"3rd. Shensi Province also produces white opium in appearance like Patna. It comes occasionally to Canton.

"4th. Kansuh Province also produces white opium, but this seldom appears.

"5th. Kwangsi Province also produces white opium, which goes by the name of 'Nan hing white,' and is consumed in Canton, but only in small quantities.

"6th. The magistracy of Sin hing, in the Prefecture of Shao-ching, Kwangtung (Canton) Province, also produces white opium called 'Paradise white' ('Tien tang pai'). The natives of the four lower Prefectures mix it with other sorts for consumption.

"7th. The inhabitants of the Ho yuan, Hai-feng, and Lien-feng Magistracies under the Huì chow Prefecture, clandestinely cultivate opium, which is made up into balls. They buy Malwa and mix it with the native into a paste, which they alone consume. It does not go elsewhere, not even to Canton.

"*Foreign opium* is distinguished as follows:—

"1st. Patna is chiefly consumed in Canton and Shanghae.

"2nd. Malwa is chiefly used on the North River of Kwangtung (Canton).

* Tael equal to 6s.; picul equal to $133\frac{1}{3}$ lbs.

"3rd. Benares is taken principally by the four lower Prefectures of Kwangtung (Canton).

"*Native.*—4th. Yünnan white circulates everywhere.

"5th. The other sorts of white Chinese opium are not much in circulation, and their distribution cannot be actually defined..

"Although it is impossible to obtain the quantities of opium grown in the various provinces of China, still the above description is sufficient to show that it is very commonly cultivated over the length and breadth of the Empire, and with little or no interference on the part of the Government, and as all the evidence obtainable goes to prove that the native production is increasing, it may fairly be assumed that the taste for it is also on the increase.

"It may be supposed that foreign opium is subjected to no further imposition of duty than that provided by the tariff annexed to the Treaty of Tien-tsin, but this is a mistake. By the regulations opium is excepted from the operation of the transit privilege, by which, on payment of an additional 2½ per cent., foreign goods are freed from the levy of barrier and interior dues. Consequently the intermediate taxation from the time it leaves the importer to the time it reaches the consumer is rather heavy and somewhat arbitrary. The following is a list of the legal dues leviable on a chest of opium:—

	T.	M.	C.
"Tariff duty per chest of 120 catties . .	36	0	0
War tax, called 'likin,' per chest . . .	13	0	3
Tich-hiang, per chest	7	0	0
Sycee premium (36 taels at 7*s.*)	2	5	2
	61	5	2

but the owner has some other little payments to make *in transitu.* The probability is, therefore, that the home-grown stands in a more favourable position than the foreign article as regards the levy of duties."

Mr. Consul Lay, Consul at Chefoo, referring to the decrease in the import of opium to that port during 1875, says:—

"It is becoming more manifest, year by year, that the cultivation of native opium is affecting the market even in this province, though, owing to the illicit character of the trade, it is extremely difficult to obtain reliable statistics. Merchants are either unable or unwilling to give definite information. There is no doubt, however, about this, that in Chefoo, and in every large town in the province, native grown opium can be freely bought in the market. I am informed, on what I believe to be reliable authority, that about 200 peculs, valued at £12,000, have been sold in this town during the past year, and if that is so in a place the most remote from the producing districts, it is easy to see that the consumption for the whole province must, on the lowest calculation, be a very considerable amount. The greater part comes from Shansi, but the cultivation of the poppy has been observed within the last few years in various districts of Shantung. The price is generally from 30 to 50 per cent. below Indian opium, though I am informed that it has lately risen from 200 or 300 to 400 cash a tael weight."

Mr. Consul Alabaster says that at the port of Hankow:—

"The returns of opium show a decrease, not that the habit of smoking is dying out to a very perceptible extent, but the cheaper native product is taking its place with those who merely look for a stimulant; and the more expensive foreign drug is daily becoming more and more surely a luxury for epicures and men of taste. It must be remembered, also, that the Customs returns in no way afford a guide to the actual consumption, the smuggling of opium being so easy that it is impossible to prevent or even to any appreciable extent check it; nor are foreign merchants generally engaged in the trade, which has passed almost, if not entirely, into the hands of natives and one or two Bombay firms."

At Newchang there is a notable decrease in the import of opium, the quantity in 1875 being only 840 piculs against 1265 piculs in 1874. Mr. Consul Adkins says:—

"This condition of the opium trade is of course due to the fact that the native-grown drug is fast taking the place of the Indian. It is almost impossible to ascertain, with any degree of accuracy, the quantity of native opium which is produced, except by noting the increased or diminished consumption of foreign drug. There is no crop; that is to say, the growth of the poppy is not, as yet, a recognized process of agriculture in this district. The man who wants to smoke opium grows his own supply; he has an overplus, perhaps, and that he brings to market. It is hard to say how long the preliminary stage of production—this living from hand to mouth—will continue. No doubt the principal difficulty with which the poppy-grower in this country has now to contend is a want of hands to collect the juice after the incisions have been made in the capsules. In the north-west portions of this district, *i.e.*, in the southern portion of Eastern Mongolia, there is a yearly increase in the area of production. This is the colonized tract of Mongolia, in which the largest quantities of pulse are produced, and which has been a good customer for the foreign imports of this port. In the province of Kirim, too, it is growing in the country on the right bank of the Sungari, which lies in the angle formed by the reaches of that river above and below its junction with the Nonni, east and south-east of Petuna. No doubt the farmers in that part will find it pay better to have their returns in opium, which is of such high value in proportion to its bulk than in millet or pulse, which they cannot always carry with profit to this, the nearest port for exportation. It is highly probable, therefore, that its production will largely increase in that district in future years. I presume, of course, that there is to be no interference from the territorial authorities. Attempts are made in a feeble way to tax the native drug, but the small quantities in which it comes to market render the collection of a revenue from it a matter of great difficulty. During the past year the average price of Malwa opium was 460 to 465 florins per picul, and the price of native opium 280 dollars for the same quantity."

A decline in the imports of foreign opium is also reported from Tamsuy and Tientsin; in the latter district three-fourths of the whole present consumption is Chinese grown. On the other hand, the Ningpo returns show a largely increased importation of Malwa opium. But even in this district the quantity of native-grown opium produced has largely increased, and the larger imports are attributed to certain advantages presented by the port.

The Sale of Milk of Sulphur.

Prosecutions took place on Wednesday at Runcorn against three chemists, named Marshall, Speakman, and Brown, for selling adulterated milk of sulphur.

Mr. Glaisyer, of Birmingham, defended, at the instance of the Chemists and Druggists' Trade Association, and said the present prosecutions would be regarded as test cases.

Dr. Bell, of Manchester, stated that the milk of sulphur purchased contained 58½ per cent., and in one case 65 per cent. of sulphate of lime.

For the defence, Mr. Pemberton, of Birmingham, and Dr. Redwood, of London, were called, who spoke to the general use of milk of sulphur, and said that it was much more beneficial on account of sulphate of lime. Messrs. Evans, wholesale druggists, of Liverpool, said they sold thirteen times as much milk of sulphur than they did of the other preparation. Milk of sulphur was known to contain sulphate of lime, and was extensively used by the medical profession.

The Bench decided to convict, on the ground that the article supplied was not that which was asked for. In each case a fine of £1 and costs was inflicted.

Mr. Glaisyer gave notice of appeal.—*Daily News.*

Attempt to Poison with a Sheep Dipping Powder.

At the Western Winter Assizes, held at Exeter, on Friday, December 22, before Mr. Justice Lush, William Dodd, 13, labourer, was indicted for attempting to administer to James Dimond Moysey, jun., a large quantity of poison, called Cooper's Sheep Dipping Powder, with intent to murder the said James Dimond Moysey, at Dartington, near Totnes, on the 7th September.

Mr. Templeton prosecuted; prisoner was undefended.

The prosecutor, a farmer, resided with his father and mother at Venton Farm, Dartington, and the prisoner was in his employ.

On the 7th September Mrs. Moysey sent one of the female servants to the flour hutch for a bowl of flour. On opening the cover of the hutch the servant saw that the bowl, which was usually kept within it, had been filled with flour, and she took it to her mistress. Proceeding to make the flour into dough, Mrs. Moysey observed some yellow streaks in it, and she inquired if anyone had been putting mustard in the flour. All denied having done so, and Mrs. Moysey, on smelling the dough, discovered that some sheep dipping powder had been mixed with it. On coming in from work, prisoner was acquainted with what had occurred, and on being asked if he knew how the powder came into the flour, he denied that he knew what sheep dipping powder was or where it was kept. The following morning prisoner would eat no breakfast, and this being observed by one of the servants he was asked the reason, and he replied that he was not hungry. Later on the girl asked him a further question respecting the powder, and he then admitted having mixed some with the flour, adding "I was tired of you all." The other servant said, "Did you put it there for me?" and the prisoner replied "No. I put it there for one." Mrs. Moysey afterwards spoke to him on the matter, and asked the prisoner if he had intended to put them out of the world, and he answered "No." These were briefly the facts of the case, and the learned counsel wished to draw the attention of the jury to the fact that as the prisoner was under the age of 14, they would have to be satisfied that the prisoner really knew that at the time he placed the powder in the flour he knew that he was doing wrong, and that he was fully aware of the evil consequences that might follow the act. If they did decide that he knew what he was about, they would then have to determine from the evidence whether or not the prisoner intended to murder anyone.

Mrs. Moysey and the two female servants were called as witnesses.

Prisoner asked no questions, and made no statement in defence.

In summing up the learned Judge pointed out to the jury that as the prisoner was under the age of 14 they were required to be satisfied that there was some affirmative evidence that he knew generally the mischievous nature of what he was doing, and this at the time he had the wicked intention the indictment alleged. It did not matter that no one was injured in the present instance; the guilt lay in the intent. Referring to the evidence his Lordship said he thought it was clear that the powder was not thrown haphazard into the flour, but was intentionally mixed with it.

The jury retired to consider their verdict, and returned into court with one of guilty, and a recommendation to mercy on account of the youth of the prisoner.

Mr. Justice Lush sentenced the prisoner to six weeks' imprisonment, and at the expiration of that time ordered him to be confined in a reformatory for three years.

Alleged Adulteration of Oatmeal.

Mr. Thomas Pearks, a corndealer, of High Street, Kensington, has been summoned at the instance of the Westminster Board of Works, the shop being in the parish of St. Margaret's, Westminster, for selling oatmeal adulterated with an admixture of barley-meal to the extent of 35 per cent.

Thomas Lightfoot, one of the inspectors under the Board, proved purchasing a quart of oatmeal of the defendant, and paying 5*d.* for it. Barley-meal was sold at 2*d.* per quart. He never heard of the analyst for Kensington refusing to give certificates in such cases. It was not a test sample.

Mr. Thomas, who defended, submitted that the Act should be construed strictly, for although a salutary one, it worked a hardship upon some people. He said there was not one sample of oats out of a hundred, out of which oatmeal was made, which did not contain an admixture of barley, and it was impossible to separate them in the manufacture of oatmeal. The defendant, who was in a large way of business, sold it exactly in the same state as he bought it.

Mr. J. B. Edwards, of Mark Lane, stated that since he heard of the summons he had carefully examined almost every sample of oats at Mark Lane, and had found grains of barley in every case in them; that barley was manufactured in Scotland as pearl and Scotch barley, and in London the pearl barley into prepared or flower of barley; that it was quite as expensive as oatmeal in its manufactured state, and was excellent as human food in sickness, and there was no pecuniary advantage in mixing it; that he had received a sworn declaration from the Scotch miller who made the oatmeal, which stated there was no barley in the oatmeal sent to him, and this was handed to and read by the magistrate. He sold it to the defendant in the same state as he received it, being simply the broker or factor in the transaction.

Mr. Bridge suggested that a sample should be sent to Somerset House to be analysed.

Mr. Thomas said an admixture of 35 per cent., was so palpable that an analysis was not necessary.

The defendant strongly wished for Mr. Cleaver, the analyst for the neighbouring parish of Kensington, to be called as a witness, for the benefit of the trade, as he did not believe the sample contained 35 per cent.

Mr. Cleaver, on being sworn, said he had examined samples of oats obtained from various places, and had always found barley in them to the extent of 15 per cent. and under. Knowing that all oats imported contained barley, he refrained from giving certificates. If he found 35 per cent. admixture he should give a certificate. He had examined a sealed sample sent to him by the defendant, and found it contained about 20 per cent of barley, not more. He should not give a certificate in a case of 20 per cent.

Eventually Mr. Bridge adjourned the summons for the sample to be analysed at Somerset House, on the understanding that there would not be a conviction in the event of the admixture being 15 per cent and not more.—*Grocer.*

Milk of Sulphur.

Sir,—I, for one, am glad to see that the Defence Association is about to justify its existence by taking up the great "Milk of Sulphur question," which, if necessary, no doubt will now be carried to the highest court; and for this reason I shall be almost glad to see that the Runcorn Magistrates are as ignorant and opinionated as some of their colleagues, and will decide that milk of sulphur is poison.

I would suggest that "Doctor" Newton and Captain Arrowsmith be subpœnaed, so that it may be ascertained on what authority this doctor asserts that if "one drachm of milk of sulphur be given to a child it will become hard, cause congestion, etc.," and that this public officer whose official position places the reputation and well being of chemists and other tradesmen to a great extent at the mercy of his discretion may inform us how and where he learnt that milk of sulphur "destroys more human lives than half a dozen plagues." The Chairman of the Dukinfield magistrates should also be asked on what authority he speaks of milk of sulphur as a "poisonous drug," or he should be taught that such epithets should not be used thoughtlessly when he is occupying a public and responsible position.

Would it be out of the way to request the prosecutors in this case to bring forward, if they can, positive evidence of the deleterious nature of the popular mixture known as milk of sulphur? Of course they will be able to command any amount of *à priori* assertion, but this is not what is wanted.

W. Symons, F.C.S.

Barnstaple, December 23, 1876.

Chemists and Druggists and the Medical Acts.

Sir,—The Leeds chemists in their discussion on the above subject seem to have made short work of it. They have formed themselves into a superior court, and Baron Bramwell is overruled. I wish to draw their further attention to the Acts.

Section 14, Act 1815, "It shall not be lawful for any person or persons to practise as an apothecary, etc., unless he or they shall have been examined," etc.

Section 20, "If any person shall, after the first day of August (1815), act or practise as an apothecary, without having obtained such certificate as aforesaid, every person so offending shall for any such offence forfeit and pay the sum of twenty pounds."

Now, what is an apothecary? The President (Mr. Yewdall) jumps to the conclusion that because an apothecary prepares and dispenses medicines, therefore, that is the whole duty of the man.

In the Act of 1815, section 14, the Court of Examiners are not only authorized but "required to examine all persons applying to them for the purpose of ascertaining the skill and abilities of such person or persons in the science and practice of medicine."

In section 40 of the Medical Act, 1858, a general practitioner and apothecary are mentioned as being one and the same. What, then, becomes of the assertion that "an apothecary was a tradesman dependent upon the physician for his occupation?" Surely the Act must have been read in the dark.

It is quite true that the 28th section of the Act states that "nothing in this Act contained shall extend or be construed to extend to prejudice or in any way affect the trade or business of a chemist and druggist," but then the Act explains itself by stating what is meant by the trade or business of a chemist and druggist, viz., "the buying, preparing, compounding, dispensing, and vending drugs, medicines, and medicinal compounds, etc." And so in the 55th section of the Medical Act, 1858, "the lawful occupation, trade, or business of chemists and druggists, etc., so far as the same extends to selling, compounding, or dispensing medicines." Is it necessary to make any further comment? To my mind the Act is clear enough. I think if the Leeds chemists reopen the discussion they may come to a different conclusion.

If a chemist act as an apothecary I can see no difference in the practice itself whether he does so in his own shop or in the sick man's house.

J. Fryer.

Batley Carr, Dewsbury, December 27, 1876.

The Hygienic Influences of the Pine and Eucalyptus.

Sir,—In the Journal for the 16th inst. Dr. F. T. Bond has made some remarks on my paper relating to the above subject which was printed in your Journal of the 2nd inst. He has charged me with all omission of mention of his "terebene," and expresses himself unable to understand this omission I will with pleasure explain, and in doing so shall be perfectly honest; I did and do not consider his product worth mention.

He has referred to the fact that in relation to this subject I made some observations at the meeting of the Pharmaceutical Conference at Bristol in 1875, but he has not at any time since disputed the truth of my statement,* which I now reproduce as expressing my unaltered convictions.

"Mr. Kingzett remarked that terebene was the name of turpentine that had been subjected to the action of sulphuric acid. He was somewhat amused to find an article on sale under the title of "Terebene, the new Antiseptic." He had purchased a pint bottle for two shillings, and had examined it with some interest. That turpentine has an antiseptic value is knowledge almost as old as the hills, but that this so-called terebene had a greater or even equal value he was not prepared to admit. It might be regarded as turpentine which had undergone some treatment which robbed it of its most important character as an antiseptic, viz., its power to produce peroxide of hydrogen. Moreover, such an antiseptic had several great objections to its use; thus its oily nature, its odour, and, above all things, its inflammable character, would militate against its employment."

Dr. Bond, in his letter, professes to abstain from any discussion regarding the nature of the active principle engendered by the atmospheric oxidation of turpentine and other aromatic hydrocarbons of the same class, but admits their hygienic influences to be due to this cause. I venture to think, as I also state decidedly, that the matter is beyond discussion. Whatever he may imagine, and other men have written, I have proved in the most absolute way, the fact that in this process peroxide of hydrogen is produced, and never ozone. I have further proved how this peroxide of hydrogen is produced, and by what other substances it is accompanied. Dr. Bond has, therefore, either not read my published researches, or if he has done so, he has failed to understand them.

Dr. Bond imagines that because his terebene smells like pine wood, it is the source of the sanitary influences I have alluded to. We know that the odour of ammonia is decidedly ammoniacal, but we are not aware that the constitution of ammonia was ascertained by reason of its smell; and as I have already pointed out, terebene has none but an initial value as either an antiseptic or a disinfectant.

I am sure your readers will agree with me, that no scientific weight is to be attached to so imponderable a thing as an odour.

Further, I should be indebted to Dr. Bond if he will have the goodness to point out to me where I can find his published researches; they are not within the compass of my reading.

I deny emphatically the statement that the value of terebene as a disinfectant and deodorizer has been amply established by its use in any way.

Referring to my antiseptic and disinfectant solution Dr. Bond writes "I shall be somewhat surprised to find it anything else than terebene under a new name." This statement is as unfair as it is unmeaning. Dr. Bond never saw nor dreamt of the existence of my product, except he has obtained it, since my publications regarding it, by

* *Pharm. Journ.*, September 18, 1875.

imitating my discoveries. Moreover, it is difficult to reconcile his statement with a previous one in which he expresses himself doubtful whether peroxide of hydrogen is produced by the atmospheric oxidation of turpentine, for my solution is one of peroxide of hydrogen and camphoric acid. I therefore hope that his discovery of the fact of my contradiction of any value alleged to appertain to terebene, and the further fact that my solution is not identical with the terebene to which he lays claim, may fill him with the surprise he anticipates.

CHARLES T. KINGZETT.

CHRYSOPHANIC ACID OINTMENT.

Sir,—Since sending you my second paper on Chrysophanic Acid Ointment,* I have had forwarded to me a copy of the Journal containing the letters written to you by Dr. Crocker and Mr. Gerrard. I was not till then aware that anyone else had made use of chrysophanic acid ointment, otherwise I should gladly have left the task of introducing it in their hands. However, Dr. Crocker states that "his experiments with Goa powder were limited to the parasitic diseases of the skin," whereas the chief object of my paper was to recommend the remedy (already long known in the tropics as an application for parasitic diseases of the skin) as one which I had found to be capable of a different, and far wider, use, namely as a valuable remedy in the more numerously occurring non-parasitic diseases of the skin. It is in this latter capacity, chiefly, that I have made use of it. I have also, but more recently, made trial of it in cases of ringworm, but I have not as yet proved it sufficiently from this point of view to enable me to contravert Dr. Crocker's statement that when thus used "it is by no means deserving of unqualified praise." It is quite possible, for all that I can at present say to the contrary, that I may come to agree perfectly with that statement. As to Dr. Crocker's views as to the proper strength of Goa powder ointment I quite concede his personal experience of having caused himself considerable irritation by two applications of ointment containing twenty grains of the powder to the ounce of lard, but on the other hand, I may refer him to my paper in the *British Medical Journal* of December 23rd, 1876, by which he will see that it is quite possible to rub in ointment containing half an ounce of the powder to an ounce and a half of lard, every morning and evening for six consecutive days, before any irritation whatever is produced, and that even in the case of a woman. Now women, have as a rule, skins which are more tender to the action of irritants than is the case with men. However, the sensitiveness of the skin to the action of any given irritant is a thing which varies very greatly in different individuals, as one who has had to apply only mustard poultices to different persons may very well know. I perfectly agree that in persons with very tender skins twenty grains to the ounce may quite suffice to produce considerable irritation even after only a couple of applications, since I have occasionally found it so.

With regard to Mr. Gerrard's comments, I think the question has been set at rest as to whether there are properly "two varieties" of so-called Goa powder by the tracing of Goa powder to the same place of origin as the Poh di Bahia, namely, to Bahia in Brazil, so that there is in fact but one variety. I am glad to find that so able a pharmaceutist confirms the observations that I made before I was aware of his experiments, namely, as to the solubility of chrysophanic acid in hot fats and oils and in vaseline, but I am unable as yet to agree unreservedly with him that "the use of benzol in the preparation of chrysophanic acid ointment as recommended by Mr. Balmanno Squire," is not necessary. In my second paper I have indeed expressed an opinion that it is not absolutely necessary, but I still think it to be at all events expedient. Mr. Gerrard states that "chrysophanic acid is soluble in boiling fats and oils in almost any proportion." Now my own observations have by no means led me to a conclusion of that kind; at the same time I have not made any exact quantitative experiments. However, I hope that Mr. Gerrard or some one else who may have the leisure will do so. What I have gone by is the depth of colour of the solution as viewed through test tubes of equal diameter, and as the pale-yellow chrysophanic acid powder forms a deep brownish-yellow solution, the depth of colour forms a pretty fair comparative test of the strength of various solutions in the absence of an exact quantitative analysis or synthesis of them. Now I find that a concentrated solution of the acid in benzol is of a much deeper colour than a concentrated solution of the acid in melted lard or in oil, the solutions being made at the same temperature (about 160° Fahr.), and that is the ground on which I still advocate the addition of a moderate proportion of benzol. However, I must freely admit that I am not prepared to say that boiling fat or boiling oil will not take up a larger proportion than boiling benzol since the boiling point of fat or of oil is of an infinitely higher degree of temperature, of course, than that of boiling benzol. However, I do not gather from Mr. Gerrard's letter that he has made any definite experiment of the kind with a view to settling that particular question. Neither, indeed, have I; but I think an investigation of that point to be a very desirable one. I trust also that Dr. Crocker will think it worth while to try the remedy in the treatment of some of the non-parasitic diseases of the skin because I think that by doing so he may probably be led to form a better opinion of it.

BALMANNO SQUIRE.

December 23, 1876.

* This paper has been received. It refers to the fact that chrysophanic acid is soluble in boiling fats; which has already been pointed out by Mr. Gerrard. Mr. Squire, however, still recommends the use of a small quantity of benzol.

EASILY PREPARED GALVANIC CELLS.

Sir,—Among the abstracts in the September number of the *Journal of the Chemical Society* is one on "Easily Prepared Galvanic Cells," by Onimus, from *Compt. Rend.* Will you allow me to draw attention to the fact, that in October, 1874, you published a detailed account of a similar battery in a paper of mine read at the Belfast meeting of the British Association? It is also noticed in the British Association report for 1874.

The only difference is that I used fustian or any stout cotton cloth, in place of vegetable parchment, which I still think preferable; but, in fact, ordinary stout paper could be used as well.

W. SYMONS, F.C.S.

Barnstaple, Dec. 23, 1876.

THE MILD SEASON.

Sir,—It may be of interest to your readers, and show the mildness of the weather, to know that in a walk I took in our neighbourhood on Christmas Day, I found twenty-three varieties of wild flowers in bloom, comprising:—

Buttercup, red-robin, groundsel, common daisy, great white ox eye, dandelion, scabius (*S. succisa*), ivy, wild mustard, rough chervil, common annual sow thistle, holly, sea campion, red dead nettle, furze, hawkbill, wild carrot, common grass, etc., and have no doubt that if I had extended my walk in different directions I could have found other varieties.

J. S. HICKS.

Looe, Cornwall, Dec. 27, 1876.

"*Gwalia.*"—See Mr. Scheffer's article on "Pepsin," vol. ii. of the present series, p. 761.

"*Justitia.*"—If we published your letter we should require an indemnification for the possible consequences.

"*Didaktos.*"—(1) The degree is granted by various bodies, each making its own conditions for conferring it. (2) Apply to the Secretary of the Chemical Society, Burlington House.

G. W. Stephens.—Hoffmann's 'Manual of Analysis as applied to the examination of Medicinal Chemicals,' published by Appleton and Co., of New York.

NOTICE.—Considerable inconvenience and disappointment are frequently caused by neglect of the regulations as to correspondence, letters intended for the Editor being sent to the Publishers or the Secretary, and *vice versâ*. A compliance with the explicit instructions published weekly over the Editorial columns will prevent delay, and the consequent annoyance.

COMMUNICATIONS, LETTERS, ETC., have been received from Mr. Langdon, Mr. Pooley, Mr. Stenhouse, Apprentice.

NOTES ON INDIAN DRUGS.

BY W. DYMOCK.

(*Continued from page* 493.)

CLERODENDRON SERRATUM.—*Local name*, BHARANGI MUL.

The root is found in the shops cut into pieces about three inches long; they vary in size, the largest being seldom as much as one inch in diameter, often very crooked and twisted; the woody portion shows well marked concentric rings and conspicuous medullary rays; it is very white and tough. The bark has a light brown epidermis; both wood and bark abound in starch. Bharangi is feebly bitter; it is said to be tonic and antiperiodic, but I have no experience of its properties. It grows in the Concan.

SYMPLOCOS RACEMOSA.—*Local name*, LODHRA.

The bark of this tree is of a light fawn colour: external surface corky and much fissured transversely; internal of a lighter colour and fibrous texture. On making a transverse section a central layer of a red colour is seen between the corky and fibrous portions. Microscopic examination shows that the coloured layer is chiefly composed of oblong cells containing red colouring matter; the inner layer of the bark consists almost entirely of woody fibre. Lodhra bark is very soft and friable; it has a faint balsamic flavour with slight astringency, and is considered by the natives to be heating and to promote maturation of the humours of the body; it is also used externally made into a paste with some adhesive substance much in the same manner as we use a pitch plaster. I have not seen any account of its trial by Europeans. It is in general use in native practice, and is kept in all the shops.

ACHYRANTHES ASPERA.—*Local name*, AGHARA.

A common weed with an erect striated pubescent stem, generally about two feet high, but sometimes much more. Side branches in pairs, spreading. Leaves pubescent from the presence of a thick coat of long simple hairs; obovate, undulated, very obtuse, acuminated; base attenuated; petiole short. Spikes long, lax; flowers green; bracts rigid, prickly. Sections of the stem of the plant do not show any crystalline deposit in the parenchyma. Aghara is a well-known simple amongst the natives in this part of India; it is used in decoction as a diuretic, and the juice as an application to scorpion stings and to relieve toothache.

COIX LACHRYMA.—*Local name*, KASSAI BIJ.

The silicious involucre of this grass containing the seed is sold in the drug shops. It is about the size, and has much the appearance, of a small cowrie shell, shining, white, and very hard. At the base is a scar marking the attachment of the peduncle; at the apex an opening, from which, even in the dry state, a portion of the female flower may be seen protruding. In the fresh state a spike of male flowers from one to two inches long rises from it. Kassai Bij is used as a diuretic.

WRIGHTIA TINCTORIA.—*Local name*, KALA-KOORA.

The drug generally consists of pieces of the root of the tree from three to four inches long, and from one inch to half an inch in diameter. The bark is of a dark brown colour externally, and is studded with numerous little warty projections; the wood is white. Sections of the bark show that the parenchyma contains many cells filled with red colouring-matter, as well as much starch; towards the inner part of the bark there are numerous large liber cells arranged in two continuous rings. Kala-Koora, when chewed, is moderately bitter; it reddens the saliva. These characters are sufficient to distinguish it from Pandhra Koora, or Conessi bark, the produce of *Holarrhena antidysenterica*, the bark of which has the following characters:—Very thick, much twisted and quilled, of a dirty white or dull buff colour, external surface marked by numerous transverse ridges, internal surface longitudinally striated, taste very bitter, does not colour the saliva when chewed. The bark of the stem of *Wrightia tinctoria* is also met with in the shops; it is smoother than the root-bark, and of a paler colour; it cannot be mistaken for Conessi bark, as it contains much colouring-matter. A full account of the botanical history of these trees will be found in the 'Pharmacopœia of India,' p. 455. The seeds of *Holarrhena* (bitter inderjow) and of *Wrightia* (sweet inderjow) are always obtainable in the shops. *Holarrhena* contains an alkaloid which has been named Wrightia.

EUPATORIUM AYAPANA.—*Local name*, AYAPANA.

A small shrubby plant, 5—6 feet high; branches straight, reddish, with a few simple scattered hairs; young shoots have a somewhat mealy appearance, due to the presence of small particles of a white balsamic exudation; leaves opposite, in pairs, their bases uniting round the stem, about four inches long and three-quarters of an inch broad, fleshy, smooth, lanceolate, attenuated at the base; midrib thick and reddish; flowers bluish. The odour of the plant is aromatic, somewhat like ivy, but more agreeable, the taste also reminds one of that plant. Ayapana is cultivated in some of the Bombay gardens. Its medicinal properties are mentioned in the 'Pharmacopœia of India.' In this part of the country it is chiefly in repute as a stimulant, expectorant, and bitter tonic.

PRUNUS Sp.?—*Local name*, HUB-UL-KILKIL.
" " " " GAVALA.
" " " " PUDMA KASTA.

These three articles evidently belong to the cherry tribe, and are imported into Bombay from Northern India, or from Arabia or Persia. The first resembles ordinary cherry stones; the almond has a brown skin and a strong prussic acid flavour. The second consists of the almonds of some kind of cherry, amongst which a few entire stones are found; these have very fragile shells of a pointed oval shape, about $\frac{4}{10}$ths of an inch long and $\frac{3}{10}$ths broad; the almonds are of a pale buff colour, the skin thin and marked with longitudinal veins; they have a strong prussic acid flavour. The third consists of the smaller branches of a kind of cherry, three-quarters of an inch, or less, in diameter; the bark evidently contains amygdalin. All three are commonly met with in the shops, and serve as substitutes for prussic acid in native practice.

DATURA Sp.?—*Local name*, GHARBHULI.

The immature capsules of a kind of thorn-apple threaded upon a string, said to be imported from Arabia. The capsules are light brown and thickly set with longish prickles; they are about three-quarters of an inch long; sometimes the peduncle remains attached; they do not correspond with the immature fruit of the Indian varieties which grow in this part of the country. The native name, which means forgetfulness of home, indicates their physiological action. Mr. Moideen Sherriff states that in Madras the flowers or buds of *D. alba* and *D. fastuosa* are sold under this name. See Appendix to the 'Pharmacopœia of India.'

TETRANTHERA ROXBURGHII.—*Local name*, MAIDA LAKRI.

The bark of this tree is the part met with in Bombay; some native works on materia medica also describe the root, but I have never seen it in the shops. The bark varies in thickness from $\frac{1}{10}$th to $\frac{3}{10}$ths of an inch; externally it has several layers of whitish, scabrous, corky tissue, the remaining portion is of a chocolate brown colour. A microscopic examination shows abundance of reddish-brown colouring matter in the parenchyma, and numerous liber and stony cells; there are no distinctive characteristics. The odour of the bark is feebly balsamic; its most remarkable property is the large quantity of mucilage which it affords when moistened; this has a bland taste, with a faint, agreeable aroma. If the bark has been long kept the aroma disappears, but the mucilaginous qualities remain unimpaired. Maida Lakri is a well-known drug, and is to be found in every shop. Its chief use is as a demulcent and astringent in affections of the bowels—such as dysentery.

TAXUS BACCIFERA.—*Local name*, BIRMEE.

The young shoots and branches of the common yew, with the leaves chopped up in short lengths of an inch, or less, are met with in the shops under this name. The tree grows in the Himalayas. Its properties are too well known to require notice here.

FLACOURTIA CATAPHRACTA.—*Local name of tree*, JUGGUM, *of the drug (leaves)* TALISPUTREE.

This tree is found in some of the Bombay gardens; it grows wild in the southern part of the presidency. The leaves are almost exactly like yew leaves, but have a highly aromatic rhubarb-like odour; they are valued as a stomachic in diarrhœa and dyspepsia.

BRYONIA LACINIOSA.—*Local name*, KAWALE CHE DOLE.

The vine is climbing. Stem smooth. Leaves palmately five-lobed, more or less deeply divided; segments oblong, lanceolate, acuminated, serrated; petioles muricated, upper surface of the leaf thickly studded with white jointed calcareous hairs rising from a calcareous areola; male and female flowers in the same axils, the peduncles of the male flowers, which are numerous, remaining until the fruit ripens; fruit round, smooth, red, with white streaks, the size of a marble. The whole plant is used medicinally; it is bitter and aperient, and is considered to have tonic properties.

(*To be continued.*)

CONTRIBUTIONS TO THE CHEMICAL KNOWLEDGE OF CULINARY PLANTS.*

BY DAHLEN.

The following analytical results are taken from Dahlen's investigations on pot-herbs (*Landwirthschaftliche Jahrbücher*, 1875, pp. 613–723).

Sprouts.—The young suckers of sprouts and of asparagus can be regarded only as luxuries.

Culinary and Potage Herbs.—The various kinds of cabbages form an excellent nutrient rich in albumin and phosphoric acid. The most proteinaceous are the small heads of the rose cabbage, which approach most nearly to the undeveloped heads of cauliflowers. The leaves of white cabbages also form an excellent nutriment. The same may be said of the leaves of spinach, which contain much albumin and mineral nutrients.

Salad Herbs.—These, like the various kinds of cabbage, are very rich in nitrogen, ash, and phosphoric acid. In the fresh state they contain about 94 per cent. of water and 2 per cent. of nitrogenous bodies.

Roots, Tubers, and Tuberous Root-stocks are generally characterized by their small amount of nitrogen and phosphoric acid. They contain, with but little crude fibre, a large quantity of extractives free from nitrogen; also about 84—94 per cent. of water.

Onions contain a sulphurized, readily volatile, strongly smelling oil.

Fruits and Seeds are the most valuable part of the vegetable nutrients, as they contain a large quantity of protein substances. Cucurbitaceous plants form two classes, one comparatively rich, the other comparatively poor in protein. The cucumbers belong to the former class of plants, and form in a certain stage of development a nutrient very rich in albumin, phosphoric acid, and potash. Proportion of nutrient, 1 : 1·5 They also contain much grape-sugar.

Melons contain phosphoric acid, also 1·3 per cent. of a liquid orange-coloured fat, and in the fresh state about 95 per cent. of water.

Gourds are poor in protein and phosphoric acid. Proportion of nutrient 1 : 6 to 1 : 8.

The fruits of the tomato (a solanaceous plant) rich in fat and grape-sugar, contain much protein.

Legumes contain the largest quantities of protein, starch, potash and phosphoric acid. The legumin forms the main ingredient of the albuminous bodies contained therein. The increase of seeds also increases the contents of nutrients. As the seeds ripen the sugar is replaced by starch, and the quantities of fat, woody fibre and water are decreased.

Juicy Fruits and Berries form non-albuminous eatables, which are valued only on account of their agreeable taste.

---

Envelopes indorsed "Pharm. Journ."

1876.

PHARMACY has not yet attained the pitch of happiness indicated by being without a history, and therefore it falls to our lot, now that eighteen hundred and seventy-six is "added to the mass of buried ages," to recount to the best of our ability the principal events recorded in these pages during the past twelve months.

As usual we shall deal first with the business that has occupied the attention of what is at present, at any rate—and seems likely to remain—the body most representative of the pharmacists of Great Britain, the Council of the Pharmaceutical Society. Very little alteration has taken place in the constitution of the Council, the only new members being Messrs. ATKINS and STACEY, chosen to fill the places of two members, Messrs. SUTTON and BAYNES, who voluntarily retired, the former after six years' and the latter after four years' valuable services. Mr. THOMAS HYDE HILLS, who for three years had presided successfully over the Society, has made way for Mr. JOHN WILLIAMS, the former Treasurer, as President; Mr. ALEXANDER BOTTLE, his valued coadjutor, has handed over the Vice-Presidency to Mr. WILLIAM DAWSON SAVAGE; and Mr. CORNELIUS HANBURY has been chosen to be Treasurer.

The subject of the examinations must always be a primary one in a review of the year, as in connection with it the best estimate can be made of the progress towards the object of the Society's charter, "of advancing Chemistry and Pharmacy and promoting a uniform system of education of those who should practise the same." It is therefore gratifying to find that although the gross number of examinations greatly exceeded that of the preceding year, being 1639 against 1166, and notwithstanding the increased stringency of the examinations, the contemplation of which almost caused a temporary panic in some quarters, the percentage of failures has been comparatively low, being on the average only 43·3 per cent. Thus there have been 1054 Preliminary candidates, with 447 failures, or 42·4 per cent., against 824 with 50 per cent. of failures in 1875. There have also been 44 certificates of other examining bodies received. The Minor candidates have numbered 482, with 200 failures, or 46·3 per cent., against 285, with 50 per cent. of failures in 1875. The Major candidates have numbered 101 with 39 failures, or 38·6 per cent., against 82 with 34·1 per cent. of failures in 1875; in this case only there has been a slight increase in the proportion of failures, but there has been an increase of 8 in the number actually passed. The decreasing number of persons entitled to claim the Modified examination has been further diminished by 27 who have passed during the year.

The questions for the Preliminary examinations of the past year have been set, and the answers valued, by the College of Preceptors, the College making its report to the Board of Examiners, and the Board reporting to the Council. To judge from an examiner's memorandum, forwarded to the Council, the acquirements of the candidates in the subjects of examination are considered by the College to be but moderate. It had been arranged that for conducting the other examinations the Board should meet only six times during the year, but to meet the wishes of some students who pleaded inconvenience by the alteration, a seventh meeting was arranged. It has been recently urged, however, that the number of meetings might be advantageously reduced to four, the meeting in October being especially objected to as occurring when no "recognized school" is open, and therefore at a time when few could go up "efficiently prepared." It seems possible that the statement may fail in convincing the Council that it is its duty to arrange the meetings of the Board to suit the "preparation" of the candidates.

At the February meeting of the Council, Mr. WILLIAMS, then Treasurer, with a view to improve the finances of the Society and lessen the pecuniary interval between the Major and the Minor, revived a proposition that the fee for the Minor examination should be raised from three to five guineas, and that for the Major lowered from five to three guineas. The total of the fees payable before attaining the title of Pharmaceutical Chemist would therefore have remained the same, but a larger proportion would have been payable for the examination qualifying to follow the calling of a chemist and druggist. He also proposed to alter the practice of returning a portion of the fee in the case of failure, in order to discourage candidates from coming up prematurely. The motion was opposed by Mr. FRAZER, and there was a general feeling that it would be inexpedient then to change the amounts of the fees, which would have required an alteration of the bye-laws. But it was agreed that after the 1st of January, 1877, no part of the fee should be returned to an unsuccessful candidate, but that he should be allowed to present himself for examination within twelve months upon payment of two guineas for the Major or Minor examination, or of one guinea for the Preliminary or Modified; after that interval the full fee will again become payable. It will not be out of place to recall here that on the same date the provision, enacted by a General Meeting of the Society in May, 1873, came into force, that a candidate for the Minor or Major examination must satisfy the examiners that he has for three years been practically engaged in the translation and dispensing of prescriptions. For that purpose a form of declaration has been prepared, which every Candidate will be required to make before being permitted to enter for examination.

At the first meeting of the Council in 1876 the subject of the prizes given annually in connection with the Society's examinations was brought forward in a report from a Committee, and it has given rise since to much discussion. It will be remembered that the competitions for the Pereira medal and the Prize of Books were formerly confined to candidates who had passed in the first divisions of the Major and Minor examinations respectively; therefore when this distinction was abolished, and the lists of names were published alphabetically, it became necessary to make a fresh arrangement. In January it was decided that the interest on the Pereira fund and the sum given annually by the Council should be expended in providing three medals,—being a silver Pereira medal, a Pharmaceutical Society's medal of silver, and one of bronze,—to be competed for by men who had passed the Major examination during the session and were at the time of passing Associates of the Society. These medals were to be supplemented by presents of books from Mr. THOMAS HYDE HILLS. The examination was to be a written one, conducted simultaneously in London and Edinburgh, and the questions were to be set by the London Board of Examiners. The prize previously offered for competition among those who passed the Minor examination was thus discontinued. Mr. GREENISH incidentally pointed out that the intention of the originators of the Pereira medal was that it should be a reward for original research and not for proficiency as evidenced by the result of an examination.

The above arrangement was not long left in peace. At the February meeting Mr. MACKAY objected that it did not put the examiners in London and in Edinburgh upon an equal footing; whilst Mr. SCHACHT saw in the necessity for men to go to London or Edinburgh for examination a disadvantage to those who lived at a distance from either city, and considered the prize examinations might be held at any of the local centres. A motion, however, to have the questions set by one member of each board was negatived. In March Mr. SCHACHT again brought forward the subject, and a resolution to refer the matter to a Committee to consider the advisability of adopting Mr. MACKAY's proposition and also of increasing the number of examination centres was adopted. In April the Committee reported recommending that the Council itself should appoint from time to time two Members of the Boards of Examiners to conduct the examinations, and against the number of examination centres being increased; this report was adopted, and the regulation then made is that now in force.

The prizes given by the Council to successful students in the School of Pharmacy have also been under discussion, upon a suggestion made by Mr. GREENISH that the silver medal given at the end of a session in the Chemistry and Pharmacy and Botany and Materia Medica classes should be competed for by students of that session only, as in the Practical Chemistry class. The subject was remitted to the Library, Museum, and Laboratory Committee, which sought the opinions of the Professors on the subject. The Professors were unanimously against the limitation, unless—a course which they would prefer—a gold medal were offered for competition between all the students, without limit to the time they may have been in the School, except that they should have attended not less than one session in each department, and at the time of competition be actually students in the School. The Committee did not report in favour of the gold medal, but recommended that a student of more than one course should only be capable of taking a prize of higher value than any he had before taken in the same class, and also that certificates of merit as well as medals should be given at the end of the short courses, and that no student should be allowed to compete for any of the School of Pharmacy prizes unless he be an Apprentice or an Associate of the Pharmaceutical Society. The Council agreed to these recommendations. By the kindness of Mr. THOMAS HANBURY the Council will be able, for some time to come, to hand to the first prizeman in each class a copy of the 'Science Papers' and 'Pharmacographia' of the late DANIEL HANBURY.

In January a lady's name again appeared on the list of candidates for election as Pharmaceutical Chemist Members of the Society. Mr. SANDFORD moved for its omission, and after some discussion, in which it was argued that the Council was bound by the vote of the Society in 1873, the motion was carried by a majority of one. In July a similar occurrence took place, but this time the new Council refused to elect the lady by an increased majority of twelve to eight.

The spasmodic activity of some so-called "medical defence associations" has forced the subject of counter prescribing upon the attention of the Council. A long discussion at the meeting in March and again in October, resulted in the passing of a resolution to the effect that the Council is prepared to consider the case of any chemist and druggist threatened with vexatious proceedings, and if the circumstances warrant to provide for his defence. This resolution seems to be sufficiently inclusive, and to imply that the Council will not stand by and see members of the trade placed in a worse position than their fellow citizens with respect to giving advice, but also that it is not prepared to countenance the improper poaching on medical preserves that is too prevalent in some quarters. Indeed we are not sure that the fussiness and fright on this point have been altogether warranted. It does not follow that because an irate practitioner, or even an "association," threatens to prosecute a few score chemists and druggists living in its locality that it will obtain the sanction of the Apothecaries' Company to do so, for that body has not yet evinced any unfair tendency in such a direction. Moreover, although Baron BRAMWELL in the case before him construed the Apothecaries Act very strictly, he gave a significant warning as to the absurdity of carrying the point too far; whilst a more recent decision shows that if the chemist and druggist keeps within reasonable bounds he has little to fear under the Medical Act.

The legality of co-operative societies selling and dispensing poisons came before the Council in August, in connection with a resolution asking that it might be tested in a law court, passed after the reading of a paper by Mr. HAMPSON at a conference of chemists and druggists held at Birmingham in the previous month. On the motion of Mr. ATKINS, seconded by Mr. BETTY, it was referred to the Parliamentary Committee. This Committee recommended that a deputation from the executive of the Chemists and Druggists' Trade Association should be invited to meet the Parliamentary Committee to hear an exposition of its views upon the subject. The interview took place, and it may be presumed that the exposition was convincing, if not satisfactory, as little has been heard of the subject since.

In August Mr. HAMPSON brought to the notice of the Council an order issued by the Board of Inland Revenue prohibiting the use of methylated spirit in pharmaceutical preparations for external use, with the exception of compound camphor and soap liniments, thus excluding aconite and belladonna liniment which were largely prepared with it for hospital use. It is not quite clear upon what law this order was based, as by the Act 29 & 30 Vict. the use of methylated spirit is prohibited only in the preparation of articles "capable of being used wholly or partially as a beverage or internally as a medicine." A deputation was appointed, which submitted a memorial to the Commissioners pointing this out and the hardship that would result to hospitals and other charitable institutions from the prohibition, and the Commissioners, "in deference to the wishes of the Council," waived their objection to the use of methylated spirit in the preparation of aconite and belladonna liniments.

In order to carry out the design of the Pharmacy Act in the protection of the public the Council has on several occasions been compelled to take legal proceedings against offenders; these, with one exception, in which the transfer of the business to a medical practitioner was undisclosed until the hearing of the case, have always been successful either in securing a conviction or else an engagement to discontinue the objectionable practices. Some correspondence that appeared in this Journal having, in the opinion of the Vice-President, Mr. BOTTLE, implied that the Council had been remiss in carrying out the Act in respect to Glasgow, he, in March, moved for an inquiry on the subject; but Mr. FRAZER disclaimed any such intention, and therefore the motion was not pressed.

The policy of the late Council with respect to the Benevolent Fund has been amply justified by a large increase not only in the number of subscribers, but also in the total value of the subscriptions. They have amounted during the past year to about £1360, being an increase of about £160 over the amount last year. Four annuitants of £30 each were elected in October, bringing their number up to 24, of whom one has since died. Besides the annuities, amounting to £620, the Council has disbursed £470 in the relief of necessitous and deserving applicants, making a total of £1090. Mr. SHAW has again attempted to persuade the Council to prohibit the use of canvassing cards and circulars by the candidates, but apparently the Council does not see its way to enforce such a prohibition when issued.

The Annual Meeting of the Pharmaceutical Society was held as usual in May, when the business was almost entirely confined to the adoption of the Report of the Council. The same evening a large number of the members and their friends dined together at the London Tavern, and the following evening the usual Conversazione was held in the South Kensington Museum, and was well attended.

The reports of the Professors respecting the School of Pharmacy have again been favourable both as to the number of students attending the Lecture Room and the Laboratory, and their diligence and conduct. The Students' Association in connection with the School is progressing well: it holds fortnightly meetings during the session, and now numbers about eighty members.

The Registrar's reports presented to the Council at the commencement of the year showed a slight decrease in the number of chemists and druggists on the Register, but a considerable increase in the number connected with the Pharmaceutical Society. It has been wrongly assumed on many occasions, for purposes of argument, that the Society represents only the "fringe" of the trade, and it has been spoken of as one-fifth, one-sixth, and even one-tenth. The fact is, that of the 13,296 on the last Register, 4383, or one-third, were connected with the Society, and 3500, or more than one-fourth, were entitled to take part in its government. Doubtless it would have been preferable to have the proportions reversed, but in the presence of still increasing numbers, perhaps there is something even in this result to be envied. The Registrar has again found it necessary to exercise the powers vested in him under the Act, and recently published a notice that the names of 283 persons, whose correct addresses were unknown to him, would be removed from the Register unless they communicated with him before the 31st of December. The result has been that 204 names have been erased.

The Library during the year has received many additions. In the list which is issued as a supplement to the present number may be observed some important works, notably some purchased from the Hanbury Fund, and several German periodicals of which the sets are being made complete. The attendance of readers has been in excess of the numbers in 1875, and the circulation of books has also increased. The shelf accommodation having gradually become too limited, it was decided to enlarge some of the bookcases. This work has just been completed, and it is estimated that shelf-room for nearly a thousand additional volumes has been provided.

The Museum has been enriched by several valuable donations. Chief of all must be placed the materia medica collection and herbarium of the late DANIEL HANBURY, presented by his executors. The herbarium will be ready for reference by the end of the present month; but the materia medica collection, which illustrates the "Pharmacographia," and also contains many rare products, has, by the terms of the gift, to form a separate collection, and still requires much labour to be spent upon its arrangement. Amongst other things Professor DYMOCK, of Bombay, has presented specimens illustrating his "Notes on Indian Drugs," and Professor DRAGENDORFF illustrations of his paper on "Ergot," both published in this Journal. The collection of crystals illustrating crystallography has also been improved. The Professors have now been supplied with specimens for lecture purposes, so that the Museum specimens may be kept intact. This arrangement cannot fail to work beneficially, as donors will have some guarantee that their specimens will be kept for Museum purposes only. The attendance both during the day and in the evening has been about the same as in the previous year.

The Evening Meetings have been moderately well attended and the supply of papers has been well kept up. To some of these reference will be again made; it will suffice here to give their titles:—"The Best Form of Blistering Liquid," by Mr. JAMES DEANE; "The Composition of Pilula Hydrargyri," by Mr. H. SENIER; "Vaseline," by Mr. JOHN MOSS; "Vaseline, and its Application to Suppository Making," by Mr. A. W. GERRARD; "The Antimalarial Properties of the Eucalyptus," by Mr. R. D. GLOVER; "Preparation of the 'Ferrous Phosphate' of the British Pharmacopœia," by Mr. REES PRICE; "Structure and Development of Pareira Stem," by Mr. JOHN MOSS; "Cosmoline," by Mr. W. A. H. NAYLOR; "Note on an Ointment containing Calomel, Hydrocyanic Acid, and Acetate of Lead," by Messrs. T. H. POWELL and J. BAYNE; "Linimentum Saponis of the British Pharmacopœia," by Mr. W. WILLMOTT; "Suggestions for a New Method of Making Mistura Guaiaci and other Similar Mixtures," by Mr. T. GREENISH; "New Mode of making Grey Powder," by Mr. A. BOTTLE; "Oleate of Bismuth," by Mr. S. C. BETTY; "Some Reactions of the Glycerole of Nitrate of Bismuth," by Mr. J. WILLIAMS; "Crystallized Hyoscyamine," by Mr. W. MARTINDALE; "Note on Impure Glycerine" and a "Note on a Crystalline Deposit from Tincture of Galls," by Mr. A. W. GERRARD; "Note on Capsaicin," by Mr. J. C. THRESH. Besides these many other subjects have been introduced informally, and the discussions have been always full of interest. The October meeting was, as usual, devoted to the Professors' reports and the distribution of prizes to the successful students of the previous session, the proceedings being brought to a close by an admirable address to the students from Mr. BARNARD S. PROCTOR, of Newcastle.

The Council of the North British Branch has been able to report favourably of its progress. The rooms have been fairly tested, and prove to afford every convenience; whilst the library and museum, to which numerous donations have been made, have been well used. At the annual meeting, Mr. WILLIAM GILMOUR was re-elected as President, and Mr. ALEXANDER KINNINMONT as Vice-President; Mr. JOHN MACKAY, also, still gives his valuable services as Honorary Secretary. The scientific meetings have been occupied in the reading of several interesting papers by Drs. CRAIG and MACADAM, Messrs. HOWIE, CLARK, BAILDON, and others. In October an experiment was commenced, with fair promise of success, in the delivery of courses of lectures on chemistry, materia medica, and botany, and demonstrations on practical chemistry, especially in connection with the Branch.

Of the usual annual gatherings the British Pharmaceutical Conference stands first in relative importance. It was held at Glasgow in September, and was ably presided over by Professor REDWOOD. Whether for the number and quality of the papers, or the arrangements of the local committee, it must be esteemed one of the most successful yet held. On this occasion it was announced that fresh grants had been made in aid of pharmaceutical research to the amount of £95. The British Association met in the same city under the presidency of Professor ANDREWS. The British Medical Association met at Sheffield in the early part of August, under the presidency of Dr. DE BARTOLOMÉ. The American Pharmaceutical Association met in Philadelphia in September, in connection with the Centennial Exhibition held there. The French Association for the Advancement of Science and the French Pharmaceutical Congress were held at Clermont-Ferrand in August. The German Apothecaries' Union met in Stuttgart in September. Though of a different nature, the Chemists' Ball, which was held in January—and which, by the way, is again due on the 17th inst.—was as popular and successful as any of them.

In July an important conference of chemists and druggists was held in Birmingham, which resulted in the formation of a Chemists and Druggists' Trade Association. It was hoped that this Association, by gathering into its membership nearly all the chemists and druggists of the kingdom, would become a powerful and permanent influence for good on behalf of the trade. How far there is a prospect of this hope being fulfilled we are not at present in a position to judge.

A suggestion made by Mr. GREENISH as to the institution of a "Hanbury Gold Medal," as a reward for original research in materia medica or pharmacy, has advanced considerably towards maturation during the year. In January Professor DRAGENDORFF, of Dorpat, communicated to this Journal some definite proposals in relation to it, and in February the Council decided that a Committee should be formed to carry out the movement; it has since received the adhesion of the presidents of several of the learned societies and many other scientific gentlemen. The subscription was limited to one guinea, and a sum amounting to about £400 has been subscribed, which will be at the disposal of the General Committee for the purpose.

The reports from the provincial associations do not evidence any marked improvement in the disposition of apprentices and assistants to utilize the means of pharmaceutical education provided for them. Many of these associations appear to be stationary, but the societies at Manchester, Nottingham and Liverpool report an advance, Manchester thus justifying a grant of £25 from the funds of the Pharmaceutical Society. On the other hand the reports from Northampton and Hull speak despondingly, whilst the Norwich association has ceased to exist. At Plymouth and Dover new societies have been started.

Turning to some events in connection with the promotion of science and scientific education it may be stated that those who are advocates of what is now generally termed "the endowment of research" have been gratified by the Government increasing the sum of money at the disposal of the Royal Society for grants to scientific men from £1000 to £4000. The success of the Yorkshire College of Science has fully equalled the hopes of its promoters; whilst the new College at Bristol has made a start. An attempt is also being made under favourable auspices to found an institute of Professional Chemists. Nor may we omit to mention the interesting display of scientific instruments that has been made at South Kensington.

The session of Parliament was not nearly so prolific of special interest to pharmacists as that of the preceding year. Sir J. D. ASTLEY's Bill, shorn, through the influence of the Pharmaceutical Society, of all its objectionable features relating to the sale of poisons, and remaining only a Bill against their administration to horses and cattle, passed into law. Legislation as to juries in Great Britain was not attempted. It may be useful here however, to correct some false impressions that have gained currency in respect to the question of the exemption of chemists and druggists from jury service. As far as this battle can be fought up to the present time, it has been fought and gained by the Council of the Pharmaceutical Society. The whole question of jury service is now waiting for legislation, and several Bills dealing with it have been introduced, more or less under Government sanction, during the last few years. In the latest of these, in 1874, owing to the exertions of the Council, provision was made to exempt all registered chemists and druggists from service. In March, the unrestricted sale of "patent medicines," was brought before the House of Commons by Colonel LEIGH, but the Government then refused to pledge itself to deal with it. Recently the Lord Advocate promised to use his influence for its suppression, but also raised some doubts whether he knew what a patent medicine was. A memorial asking that the sale of poisons under the Patent Medicine Act may be assimilated to their sale under the Pharmacy Act, 1868, has been drawn up in Exeter; the advisability of this course has also been frequently urged in the correspondence columns of this Journal, but the subject has often been encumbered there with propositions to confine the sale of patent medicines, as such, to chemists and druggists, an object that is not at all likely to be attained. Sir WILLIAM FRAZER has given notice that he will introduce a poisons bill next session, but has shown no sign as to what its nature will be. Sir THOMAS CHAMBERS again brought forward the subject of civil service trading and was met by a count out. The regulations for carrying out the Registration of Trade Marks Act were issued at the commencement of the year. In consequence of the great number of existing trade marks it was found impracticable to register them all by the time fixed, July 1, after which proceedings could not be taken for the protection of an unregistered trade mark. A short Act was therefore passed prolonging the time until the 1st of July, 1877. The Registrar of Trade Marks has been sustained by the High Court of Justice in an objection to register as a trade mark a word which was not so used before the passing of the Act; it has also been decided that the word "registered" cannot be considered as a part of a trade mark.

Several prosecutions instituted in Glasgow by the Excise for the sale of an article called "Liebig's Liquid Extract of Meat" without a wine license caused some sensation, which was heightened by a confusion of that preparation in the newspapers with the ordinary extract of meat; a modified penalty was imposed in each case. Several persons who had failed to ensure that their "finish" contained the proper quantity of resin have also been fined. Further, it has been demonstrated by the Excise that in Glasgow methylated spirit is sometimes used as a beverage, and that it is probably sometimes sold for that purpose. From Ireland, too, the practice of ether tippling has been again reported, and one death has resulted from it. Lastly, the Excise has been successful in a prosecution for the sale of "corn solvent" without a stamp, a result that necessarily led to the reversal of a decision of the Board itself that a very similar preparation could be sold without one.

During the year 80 cases of fatal poisoning have been recorded in this Journal; the poisonous agents and the number of deaths due to each being as follows:—aconite, 2; annatto, 1; antimony, 1; carbolic acid, 6; chloral hydrate, 8; chlorodyne (Towle's), 1; cordials for children, 5; cyanide of potassium, 6; "fly oil," 1; hydrochloric acid, 3; laudanum, 11; liniments, 3; liquor potassæ, 1; lotion, 1; mixtures, 5; morphia, 2; œnanthe crocata, 2; opium, 3; oxalic acid, 2; paraffin, 1; phosphorus, 1; prussic acid, 6; strychnia, 2; vermin killer, 4; white hellebore, 1; yew leaves, 1. This list shows a considerable increase upon those recorded in the previous two years, in each of which the number of cases was only 46. But how far this is due to an actual increase in the number of cases of poisoning in this country or to the increased vigilance of our friends in keeping us informed of the inquests we are unable to say; we are inclined to attribute it chiefly to the latter cause. Still in considering what may be termed the more notable cases of last year, such as have probably been recorded almost without exception in other years, there is much that is very suggestive. Five deaths have resulted from mistakes in connection with the dispensing counter: two of them (one in a surgery and one in a chemist's shop) arose from confusion of the bottles upon the counter after making up; two (one in a surgery and one in a dispensary) were mistakes in dispensing, and one the selling by a chemist of a poisonous for a non-poisonous substance, apparently part of unexamined old stock. Of the eight deaths from chloral hydrate seven were the results of overdose taken by persons in the habit of using this compound as a narcotic. The comparative frequency of similar occurrences has led the medical press almost without exception to suggest that chloral hydrate should be included in the schedule of poisons, and the same recommendation has been made by the juries at three inquests held during the year. Similar recommendations have been made with respect to narcotic cordials for infants, which have caused five deaths. Of the eleven deaths from laudanum at least eight have been suicides. The four recorded deaths from vermin killer were all suicides. A singular fatality has attended the use of carbolic acid: twice it has been mistaken for wine (once in a hospital), once for a cough mixture, and once (in a prison infirmary) for a diarrhœa mixture. Hydrochloric acid also was drunk for whiskey! On one occasion a jury attributed a death to the size of a spoon used for measuring the medicine, an incident that lends weight to a discussion that has been going on as to the variations in this household measure. Besides the foregoing it is worth mentioning that cases of poisoning by tincture of pellitory and Virginia creeper, in which the patients recovered, have been recorded.

The year has not passed without revealing that great ignorance of the law with respect to poisons still exists where it might least be expected. Only a few weeks since a learned lecturer on chemistry was reported to have made before a learned judge the novel suggestion that some restrictions ought to be placed on the sale of vermin killers, both of them being apparently unaware that restrictions already exist under which the number of deaths from vermin killer have, as shown again this year, notably decreased. In September, too, the trade was a little surprised to learn, upon respectable legal authority, that the regulations as to entry of sale, etc., applied to all the poisons in the schedule, instead of being limited to those in Part 1. This absurdity, however, was "no sooner blown but blasted."

The Sale of Food and Drugs Act of 1875 has on the whole passed through the crucial test of a first year's history creditably; the most objectionable occurences in connection with it hitherto having been defects in its administration rather than necessary results from faulty construction of the Act. Thus the Act cannot fairly be held responsible because a public analyst preferred to depend upon his sense of smell for the detection of methylated spirit in whiskey, or because a medical education did not appear to help a chairman of petty sessions to distinguish between "hydrated sulphate of lime" and plaster of paris, or prevent him from propounding an extraordinary theory respecting infant mortality that only a subordinate official would be *gobemouches* enough to adopt. But there is a Nemesis to avenge the perpetration of such absurdities. In the one case a public society declined to admit the orthodoxy of the olfactory school, and excommunicated its professor; in the other, it has been since stated, on respectable authority, that the magistrate was by his servants himself doing—unwittingly, it is to be hoped—what he had denounced as almost a deadly crime when done by others. Another extra legal inconvenience arose in January from the premature publication of certain statements included in a report of the Sheffield Borough Analyst to the Town Council. Not only was such discredit as would properly attach to persons convicted of an offence under the Act thus scattered broadcast amongst the whole of the pharmacists of Sheffield, heightened by sensational "leaders" in the public press, but the means specially provided in the Act for testing whether any offence at all had been committed were not available to those who suffered from the effects of the vague imputation. The public analyst disclaimed being held responsible for the publication of the report; the Town Council refused to carry the cases into court; and the Sheffield pharmacists had to be content with the knowledge that—

"Some one had blundered."

A similar injustice, but on a larger scale, nearly resulted from the somewhat incautious announcement of a paper for an evening meeting of the Pharmaceutical Society. Upon the reception of the paper itself, however, it became evident that it would be impolitic to favour the usurpation of the duties of the responsible public analyst by an irresponsible candidate for such an appointment, or to substitute the lecture theatre at Bloomsbury Square for the police court in the hearing of cases of alleged adulteration. The paper therefore was declined and although it was afterwards read before a provincial philosophical society it soon sunk into the oblivion which it merited.

The provision for referring disputed cases to the chemical staff of the Inland Revenue laboratory seems to work satisfactorily, the decisions, with a notable exception in some butter cases, having generally received acquiescence. During the year the penalty for refusing to sell has been several times imposed, and a written warranty has been the means of transfering the responsibility from the retail to the wholesale dealer. A difficulty in the construction of the Act at one time occurred to a London magistrate, who seemed inclined to hold that the sale of an adulterated article to an inspector was not to his prejudice, as it was not for consumption; but this objection appears to have been quietly dropped. Also, it has been held that when a mixed article is sold, such as mustard condiment, it is not sufficient for a statement of its nature to appear on the package in bulk, but it is required to be placed on every portion sold.

Of the prosecutions for offences against the Act, those relating to the sale of milk of sulphur are doubtless of the greatest interest to our readers. It has been decided in different localities that it is, and that it is not, legal to sell the "lac sulphuris" of the London Pharmacopœia, 1721, as "milk of sulphur," and one magistrate has taken the opportunity of deciding both ways. However much opinions may differ as to the advisability of abandoning the old preparation, it is at least unfair that those who wish to see the question as to the legality of its sale cleared up should be charged with favouring adulteration, especially as it cannot be denied that when it is supplied for milk of sulphur in many districts it would be of the "nature, substance and quality of the article demanded" by the purchaser. The possibility of the settlement of the question in connection with cases now under adjudication is therefore a subject for congratulation. There has been a conviction for the sale of sulphuretted antimony for precipitated sulphur, and the same person was fined for putting 50 per cent. more iodide of potassium in a mixture than was ordered in the prescription. In a prosecution for the sale of pepper contaminated with bean meal, the plea that the pepper was unavoidably mixed with extraneous matter during the preparation—the stones used for grinding it having been previously used for bean meal—was disallowed, the Bench considering the admixture could have been avoided. A prosecution for the sale of "ginger ale," on the ground that it was not ale, was unsuccessful.

As in former years scientific literature has gained by the increased attention that has been paid to the detection of sophistications in food. Butter has taken the chief place. A return made to the House of Commons, by the Principal of the Inland Revenue Chemical Laboratory, gave the results of the examination of a very large number of samples of butter. From these Mr. Bell inferred that the determination of the specific gravity of butter fat in the liquid condition at 100° F. could be used as a test of its genuineness, since the specific gravity of ordinary animal fats was found to vary at that temperature between 902·8 and 904·5, whilst that of butter fat rarely fell below 910·0. It was also noticed that when a sample of inferior butter was kept in small quantities in glass or earthenware vessels, it showed a tendency to lose the characteristic principles of butter, and to become assimilated to ordinary animal fat. The sufficiency of the specific gravity test alone has, however, been challenged by Messrs. Angell and Hehner and Dr. Dupré. The latter chemist considers that whilst a reputed butter, showing a specific gravity below 911, might safely be pronounced adulterated, a higher specific gravity would not necessarily indicate purity, since by heating mutton dripping for some time at 300° C., its specific gravity was raised from 904·8 to 914·4, whilst one sample of mutton dripping reached 917·3. Mr. Pinchon has described an instrument for taking simultaneously the specific gravities of oils and their temperatures, and using them as indications of purity. Professor Redwood has described an arrangement for the determination of the melting points of butter and other fats. Further, Dr. Dupré's researches have shown that the deficiency in the proportion of insoluble fatty acids in butter compared with other fats is partly made up by the presence of 5 or 6 per cent. of fatty acids soluble in water. The sensational talk, too, about the adulteration of whiskey with methylated spirit and fusel oil led Dr. Dupré, whilst disclaiming belief in the prevalence of such adulterations, to publish a method for their detection, based upon the different products obtained by oxidation of the various alcohols.

Amongst other papers on analogous subjects, may be mentioned Dr. Wittstein's on the testing of coffee, one on the examination of spurious beeswax, Mr. Clark's on the use of the microscope in the detection of seed constituents in colocynth powder, and Mr. Greenish's on how to use the microscope in the detection of an adulteration of maranta with cassava starch. And whilst speaking of microscopical work we must mention Mr. Moss's thorough histological investigation of pareira stem. Dr. MUTER has published a method for the detection of castor and other fixed oils in balsam of copaiba, based on the different solubilities of the sodium salts of oleic and copaivic acids. The presence of gurgun balsam, or "wood oil," in balsam of copaiba can be detected, according to Professor FLUCKIGER, by the splendid violet colour produced when it is dissolved in carbon bisulphide and a mixture of sulphuric and nitric acids added; fish oil and oil of valerian, under the same treatment, give a more transient violet colour. Professor DYMOCK has shown that sulphuric acid may be used as a test for the genuineness of chaulmogra oil. Further, Mr. GILMOUR says, that the amount of cetin liberated from sperm oil by the action of sulphuric acid may be taken as an index of its purity. He has also suggested that the chlorophyll bands given in the spectroscope by olive oil, and other vegetable oils, might be used for a similar purpose. M. BRETET has stated that genuine dragons' blood may be distinguished from false by its giving off red fumes when heated, the imitation not doing so. While searching, too, for suspected lead colouring in sweets, Mr. STODDART lighted on a delicate test for saffron. Some progress has been made, also, towards converting a popular belief as to the application of coculus indicus into a popular fallacy, the Inland Revenue authorities reporting that although special efforts have been made to discover any use of this drug as an adulterant of beer they have been unsuccessful, whilst inquiries have shown that the quantity retained in this country is used mainly in poisoning fish and making cattle ointment.

In the literature of the pharmaceutical sciences for 1876 salicylic acid has undoubtedly taken the lion's share. Professor KOLBE has continued his investigation into its power of arresting fermentation. This appears to be especially great in the case of beer yeast and similar ferments, 140 parts of yeast failing to cause fermentation in the presence of 1 of salicylic acid. The amount of sugar present has no influence, within certain limits, upon the result. Neither can yeast resume its functional activity after being checked by contact with the acid, but the amount of yeast rendered inert varies with the degree of its dilution by the fermentescible liquor. The action of salicylic acid on emulsin is not nearly so powerful as on yeast, but emulsin is coagulated to a certain extent, after which it is without action on amygdalin. Benzoic acid was found to act similarly, but in a less degree. Mr. HUNTER reports partially confirmative results, but his experiments did not prove that salicylic acid is a preventive of fermentation in sugar solutions containing much vegetable matter. NEBAUER'S statement, however, was confirmed that it prevents the fermentation of grape juice in a marked degree and for an indefinite time; it also prevents the decomposition of lime juice. But, all things being considered, Mr. HUNTER thinks salicylic acid is not so well adapted as alcohol for the preservation of the Pharmacopœia infusions. Many industrial applications have already been suggested for salicylic acid: for instance, in the preservation of meat, butter, milk, wine, vinegar, size and other readily decomposable substances; in the manufacture of glue and gelatine, as it appears to facilitate the conversion of the tissues into gelatine; in tanning, where it not only favours the action of the tanning materials, but it prevents the formation of gallic acid; and in the manufacture of writing inks and perfumery. But it has found, also, a most important use in medicine from the power possessed by it and its salts, in common with salicin, to reduce the temperature of the body in febrile cases, and their almost specific action in rheumatic fever; it has also been used for antiseptic dressings. As it had been shown that some of the antiseptic properties of the acid were modified when it ceased to exist in the free state, doubts arose as to the efficacy of the salts, when used in medicine. Professor BINZ, however, considers that the carbonic acid continually liberated in the animal tissue has the property of setting free the salicylic acid from the soda salt; nevertheless some experiments by Mr. BENGER went to show that when salicylic acid is administered it is not excreted in an active state. This use of salicylic acid in medicine and its relative insolubility have exercised the ingenuity of pharmacists. Glycerine, borax, sodium phosphate, ammonium citrate and acetate, and potassium citrate have been recommended for use to increase its solubility, but it is not clear what compounds are the result. Mr. WHITE recommends a pill mass of the acid with borax, glycerine and tragacanth. Dr. HAGER has called attention to the fact that much impure sodium salicylate is now met with, and the difficulties attending its preparation in the pure state led Mr. WILLIAMS, at the Pharmaceutical Conference, to describe the sodium sulphosalicylate, a salt in which the salicylic radical appears to exist intact, and which presents the advantage of crystalling readily and being very soluble in water. Salicylate of iron has been recommended as a substitute for perchloride of iron. Cresotic acid and sodium cresotate have been ascertained to possess properties similar to those of salicylic acid.

Cinchona bark and its alkaloids have naturally also occupied much attention. The startling statement that the Dutch have produced in Java a calisaya bark that yielded 13·25 per cent. of quinine, equal to 17·86 of the sulphate, has shed fresh light upon what the result of the cinchona acclimatization experiment may be. From some cause, probably climatic, plants from the same lot of calisaya seeds have not prospered in India, where the best average bark seems to be obtained from *C. officinalis*, yielding about 6 or 7 per cent. of quinine. The harvest of bark from the Sikkim plantations has this year amounted to upwards of 200,000 lbs., or more than twice the total previous yield. As most of this is succirubra bark, in which cinchonidine and cinchonine predominate, a mixture of the alkaloids has been manufactured from it, and supplied to medical men to experiment with as a febrifuge. At present the result is not quite clear, since some reports quoted from the *Neilgherry Courier* a few weeks since were decidedly unfavourable, whilst those quoted in Dr. King's manual, since received, are all favourable. In Sikkim the method of harvesting by decortication and "mossing" has failed owing to the predilection of ants for the young bark, and it is doubtful whether rooting up of the plants will not prove more profitable than coppicing, the root bark being comparatively rich in alkaloids. The results of special manuring have not been encouraging. The Japanese are now attempting the acclimatization of cinchona, having been supplied with seeds from Java. An unfavourable report has been received of a similar experiment in New Caledonia, and in St. Helena the attempt has been abandoned. The determination of quinine in various mixtures has been dealt with in several papers. Mr. ALLEN concentrates the solution, adds ammonia, and extracts with ether, obtaining the quinine upon evaporation as a monohydrate. Mr. PALMER, besides preferring chloroform to work with, says when ammonium citrate is present, as in ferri et quinæ citras, ether does not always remove all the quinine, but that chloroform does. Such a result, however, Mr. COWNLEY would attribute to imperfect manipulation and points out that it is necessary to shake with ether a second time. Mr. COWNLEY also finds that freshly prepared quinine sulphate probably contains 7½ molecules of water, which quantity upon exposure to the air is rapidly reduced to 2 molecules; at 100° C. the salt becomes anhydrous, but upon exposure reabsorbs 2 molecules of water. Dr. HESSE has referred aricine, cinchovatine, and the lævo-rotatory base obtained by Dr. DE VRIJ from Jamaica bark, to more or less impure states of cinchonidine. A phenol sulphate and a phenol hydrochlorate of quinine have been described by Messrs. JOBST and HESSE, and the arabinate of quinine has been recommended for hypodermic injection. Mr. CATILLON has pointed out that glycerine prevents the reaction between preparations of cinchona and salts of iron; also that its solvent action on cinchona bark is very great. The latter point has been confirmed by Mr. ANDREWS, who proposes a Glycerinum Cinchonæ.

Although Dr. BILLINGER has carried the history of opium far back into antiquity, the whole of its tale is not yet told. Dr. WRIGHT has discovered in it yet another alkaloid, oxynarcotine, and Mr. BROWN has found in it free acetic acid. An elaborate criticism of the methods of assaying its morphia value, by Mr. CLEAVER, and a note by Mr. PROCTOR, show that probably no one method will ever be applicable to the infinite variety of conditions in which opium is met with. And yet how important this point is has been shown by Mr. DOTT in the varying proportions of active principle found by him in galenical preparations of the crude drug. Consular reports show that China has become a serious competitor with India in the production of opium, although the Chinese product is not relished so much by the smoker. Neither is Persian opium, which after a relapse is again being produced in considerable quantity, so well liked by the epicures, its oiliness being objected to. Adulteration of the Persian opium, too, has already injured its character, and its variability is evidenced by Mr. D. HOWARD obtaining 10·4 per cent. of morphia from one specimen, while another yielded Mr. PROCTOR only 0·25 per cent. With respect to morphia Mr. MERCK has pointed out that the acetate becomes gradually less soluble when kept, through the elimination of acetic acid.

In describing *Rheum officinale*, which he still considers to be one source of true rhubarb, Professor FLUCKIGER gave an interesting sketch of the history of that drug, a service that he has also performed for several others. One of the principles of rhubarb, chrysophanic acid, has recently been employed by Mr. SQUIRE in place of the crude "Goa powder," of which it is the chief constituent. Mr. SQUIRE used an ointment prepared by dissolving the acid together with lard in hot benzol; but Mr. GERRARD says that the benzol is unnecessary, chrysophanic acid being soluble in hot fats. Emodin, another constituent of rhubarb, has lately been asserted to be identical with the so-called frangulin or frangulic acid, present in *Rhamnus frangula* bark. This lead to the remark that black alder bark should not be used until it is a year or two old. Gelsiminic acid has been similarly found to be identical with æsculin.

Ergot and rye are generally spoken of in association; but Mr. WILSON, in an interesting paper describing the conditions favourable to the growth of ergot, says that in Aberdeen and Kincardine shires it is rarely found on rye, although it occurs freely on twenty different grasses. Its active principle is still fertile of disputes. Mr. TANRET reported that he had obtained from it a new alkaloid, which he called ergotinine. Professor DRAGENDORFF, however, in describing several definite compounds obtained from ergot, one named sclerotic acid being claimed to be the active principle, stigmatized ergotinine as an indefinite substance. This has since been denied by Mr. TANRET, and there the matter rests. The aconite principles also remain in a similar state of haze. By using tartaric acid and avoiding a high temperature, as recommended by Mr. DUQUESNEL, Dr. WRIGHT has obtained a crystalline alkaloid sufficiently pure, he considers, to warrant him in attributing to it the formula $C_{33}H_{43}NO_{12}$, but whether Mr. GROVES'S "inert alkaloid" is a product of decomposition or not, he now seems to think doubtful.

From jaborandi, which in the previous year caused so much sensation, Mr. KINGZETT has obtained an alkaloid to which he attributes the formula $C_{23}H_{34}N_4O_4,4H_2O$, but appears to doubt whether this is identical with the substance called "pilocarpine" by Mr. GERRARD. Mr. HARDY finds that his alkaloidal substance is present in the bark as well as in the leaves, but not in the wood; he has also isolated a hydrocarbon which he has named "pilocarpene." From coto bark Mr. JOBST obtained cotoin, a crystalline principle said to be a specific for diarrhœa; succeeding parcels of bark did not yield this principle, but another, paracotoin, which also has antidiarrhœic properties. Sicopira, another Brazilian tree, is also reported by Dr. PECKHOLT to yield a crystalline principle effective against diarrhœa. Hyoscyamine in the crystalline form is now in the market, and the preparation of crystalline hydrobromate of conia has been described. Sassy bark has yielded a crystalline poisonous alkaloid, erythrophleine, and *Sium latifolum* another, together with a poisonous neutral principle. Walnut leaves have yielded juglandine, also an alkaloid; and Mr. BULLOCK has arrived at the conclusion that jervia is the only alkaloid present in *Veratrum viride*. Mr. DELLESME attributes to an alkaloid the toxic action of pyrethrum flowers, whilst Mr. ROTHER considers it to be due to persicin, one of three acid principles obtained by him from Persian insect powder. From capsicum fruit Mr. THRESH has isolated a powerfully pungent principle that he has named "capsaicin," to which Dr. BURI attributes the formula $C_9H_{14}O_2$. Normal beer proves sometimes to contain a substance resembling colchicine. Mr. COWNLEY has thrown doubts upon Professor SONNENSCHEIN'S reported conversion of bromine into strychnine. Lastly, Dr. SCHMIDT has confirmed Dr. TILDEN'S formula of $C_{16}H_{18}O_7$ for the anhydrous aloins, whilst some experiments led Mr. DOBSON to the conclusion that although the aloins are not inert they are not very active, barbaloin being perhaps most active. All this shows that there is much more to do before the time for using definite chemical principles only, as shadowed forth by the Belgian congress, will arrive.

Although no vegetable substance has been brought forward this year with very imposing claims for a place in the materia medica, several have been mentioned that may be classed as new or little known remedies. Thus *Grindelia robusta* has been recommended for use in asthma, and as an antidote to the poison of the poison oak; princewood bark as a stomachic tonic; kava kava, the root of *Piper methysticum*, in gonorrhœa; watercress as an antiscorbutic; *Asarum canadensis* as an aromatic; *Ailanthus glandulosa* in dysentery; *Megarrhiza californica* as a cathartic, though rather a drastic one; *Xanthium spinosum* as a specific against hydrophobia, though it is reported to have failed to sustain the claim; *Eriodictyon californicum* for pneumonia and chronic lung disease; and the "quinine flower" of Florida for purposes to which quinine is usually applied. Professor DYMOCK has indicated several Indian drugs worthy of closer investigation. Sir ROBERT CHRISTISON has reported his personal experience of the property of coca leaves to prevent fatigue; but different results were obtained by Mr. DOWDESWELL. *Eucalyptus globulus* has maintained its antimalarial reputation, and has been recommended as an insectifuge. Mr. HOLMES has referred the American remedy damiana to species of *Turnera* and *Haplopappus discoideus*. Dr. MILLER has compared the behaviour of mesquité gum with that of gum arabic, for which he thinks it may be substituted in many purposes of the pharmacy. Mr. PELTZ has described a new variety of liquorice extract.

At one of the evening meetings Mr. REES PRICE alluded to the fact that phosphate of iron is not so insoluble in acetic acid as is generally assumed, and gave some details as to the loss occurring in working the B. P. process for ferri phosphas. To avoid this he proposed to substitute for the acetate of soda ordered an excess of phosphate of soda. In an exhaustive paper read before the North British Branch Mr. HOWIE described the various precipitates that trouble makers of "syrup of the phosphates," and discussed their causes; he also stated that the syrups of some makers do not contain the amount of phosphates represented on the label to be present. At the Pharmaceutical Conference Mr. HOWIE again brought the latter point forward and suggested that an attempt should be made to fix what should be considered the standard strength of compound syrup of the phosphates (Parrish). Dr. JEHL has given a formula for syrup of chlorhydrophosphate of iron and lime. Mr. ROTHER has described "ferric citrophosphate," and pointed out that free orthophosphoric acid is incompatible with the stability of citrophosphoric compounds. Mr. ROTHER has also described an ammonio-citrate of iron and bismuth. Two other new preparations of bismuth have been brought forward, the oleate, by Mr. BETTY, and the glycerole, by Mr. B. SQUIRE. Mr. SQUIRE has also proposed to substitute a glycerole of subacetate of lead for the official solution, and also to use it in the preparation of the ointment.

"Blue pill" has been the subject of an investigation by Mr. HAROLD SENIER, his results seeming to indicate that the proportion of mercurous and mercuric oxides in it increases with age. Mr. BOTTLE has described a ready way of making "grey powder" by shaking the ingredients together in a bottle, and Mr. GOODALL has stated his experience that a moderate trituration is more effective in extinguishing the mercury than a more vigorous one. A soluble mercurial albuminate for use in hypodermic injection is due to Professor BAMBERGER. Mr. DEANE has given a formula for blistering solution, substituting acetic ether for acetic acid. The darkening which takes place when hydrocyanic acid comes into contact with calomel has been shown by Messrs. POWELL and BAYNE to cease when a certain quantity of hydrochloric acid has been liberated, and to be prevented altogether by the presence of sufficient free hydrochloric acid in the first place. Professors SCHWARZENBACH and FLUCKIGER have studied the curious reaction between iodine and white precipitate in the presence of alcohol, with the formation of iodide of nitrogen; and Mr. RICE has noticed that iodoform is another of the products of the decomposition, and that the iodide of nitrogen is not formed when carbolic acid is added. Mr. DARLING has noticed, also, the formation of iodoform in the so-called colourless tincture of iodine. A method for the volumetric estimation of carbolic acid with titrated bromine water has been given by Dr. KOPPESCHAAR. Mr. SIEBOLD has pointed out that in preparing precipitated sulphur the partial precipitation resulting from an insufficiency of hydrochloric acid is purer than when the whole is thrown down. Messrs. KRAMER and PINNER have shown that the substance known as "croton chloral" is really butyl chloral, as it contains two more atoms of hydrogen than was supposed. Mr. SAUNDERS is of opinion that in the liquefaction that takes place when chloral hydrate and camphor are triturated together, camphor acts the part of solvent. The action of chloral hydrate as a disinfectant has been pointed out by Dr. CRAIG. Dr. DAVY has found molybdic acid to be a very delicate test for alcohol, and, *pace* Dr. RICHARDSON, methyl alcohol has been ascertained by Mr. BEAUMETZ to be more poisonous than ethyl alcohol. In his important contribution to the history of essential oils Professor DRAGENDORFF has, in the light of innumerable experiments, discussed how far their solubility in alcohol can be used as evidence of their genuineness, the effect of age on essential oils, the restoration of resinified oils by distillation, and the colour reactions of essential oils with various substances. Mr. KINGZETT has continued his researches on essential oils, and by the atmospheric oxidation of turpentine obtained a solution containing peroxide of hydrogen and camphoric acid, which he claims to possess considerable antiseptic and disinfecting properties.

We must now be content with the simple enumeration of a few other subjects of interest in the pharmacy. As vermifuges there have been described compounds of santonin and soda,—santonin, soda and albumen,—and santonin and carbolic acid. The conversion of a portion of cane sugar into grape sugar in the early part of the preparation of syrup of ferrous iodide is said to prevent subsequent change; citric acid has been found to be without preservative influence on the syrup, and hypophosphorous acid to restore it when altered. Storax has been recommended for the preservation of lard, and mustard oil as a substitute for it. Vaseline has obtained considerable acceptance as a basis for ointments. Soap, guaiacum, glycerine and liquorice powder,—mucilage and powdered sugar,—and yellow resin,—have been recommended as excipients for phosphorus pills. A chloral cream and a chloral plaster have been described; also a compound of cod-liver oil and ferrous iodide, and the making of nitrate of zinc pencils. Ice has been recommended as a vehicle for the administration of medicines. Pancreatin has been found to have therapeutic activity, but to be inert in the presence of pepsin; peptone and peptone chocolate have also been referred to. Perhaps the latest novelty is "serum sanguinis exsiccatum." Last, but not least, pharmacists are indebted to Mr. CORDER for the drawings and description of his pharmaceutical apparatus.

Besides these papers pertaining to more or less pharmaceutical matters, we have been enabled to reproduce during the year many of a wider and lasting interest. Amongst these were Professor TYNDALL's lecture on the optical deportment of the atmosphere in reference to the phenomena of putrefaction and infection; Mr. WILLS on the relation of the atmosphere to plant life; Mr. PROCTOR on the effect of flexibility on the working of chemical balances; the Warden of the Standards on the ancient standard weights of Babylon and Assyria, and on MENDELEEF's New Balance; Professor EBER's translation of an ancient Egyptian medical papyrus; Mr. SORBY on the size of molecules; Mr. WALLACE on surface biology; Mr. KINGZETT on the chemistry of the brain; Professor DE CANDOLLE on a dominant language for science; Mr. PERKINS on the tar colours; Mr. CROOKES on the radiometer; Dr. C. W. SIEMENS on the action of light on selenium.

Of new books on subjects allied to pharmacy, there have been no lack. Dr. TILDEN has given us an Introduction to the Study of Chemical Philosophy; Professor DITTMAR a Manual of Qualitative Chemical Analysis; the veteran Mr. SMITH a History of Ferns; Mr. HOWARD the conclusion of his splendid work on the Quinology of the East Indian Plantations; Dr. M. C. COOKE a Catalogue of Indian Oils; the executors of the late Dr. CRACE-CALVERT his work on Dyeing and Calico Printing; and the executors of DANIEL HANBURY his Science Papers; Dr. HOOKER a Science Manual of Botany; Dr. MOREL a French Translation of DRAGENDORFF's

Chemical Analysis of Active Drugs. There have also been the Year-Book of the British Pharmaceutical Conference for 1875, and the Transactions of the American Association for the same year. The regular issue of the Medicinal Plants of BENTLEY and TRIMEN has also been continued. There have also been new editions of ATTFIELD'S Chemistry, TAYLOR'S Poisons, ROYLE'S Materia Medica, and HASSALL'S Food Adulterations, and a fresh reprint of the British Pharmacopœia.

We cannot close this record without a tribute to the dead. WILLIAM TAIT, a valued examiner, and his partner, JOHN SIMPSON, have been lost to the Pharmaceutical Society and to the North British Branch especially. THOMAS ARCHER DORVILLE BREW, a former member of the Council, and JOHN PALMER TYLEE, WILLIAM WOODS, and MATTHEW HUSBAND, after doing good service as local secretaries, have passed away. These have been the riper fruit; but it is sad also to record that two of the silver medallists of the previous year, GEORGE GREEN and HENRY ELLIS, did not live to wear their honours a short twelvemonth. In HENRY LETHEBY England has lost a well known chemist. MICHAEL DONOVAN is gone from Ireland but leaves his mark upon the Pharmacopœia. THOMAS DRYDEN MOFFAT, lecturer in materia medica and formerly president of the local association, is regretted by the chemists and druggists of Glasgow. In France, ANTOINE JEROME BALARD, the pharmacist who discovered bromine, and CHARLES SAINTE-CLAIRE DEVILLE, the discoverer of anhydrous nitric acid and the amorphous form of sulphur, are no more, and the Paris School of Pharmacy has lost Professors BUIGNET and GOBLER. HLASIWETZ is mourned in Germany. Lastly MC IVOR no longer watches the cinchona plantations of Southern India.

And now our task is ended! Not that the materials are exhausted, but sufficient has been said to show the multiplicity and variety of topics that are brought before the pharmaceutical world in these pages in the course of one year. *Quot homines, tot sententiæ,* is a true saying, but in the diversity here shadowed forth we think it may be assumed that there is matter of interest to every pharmacist who chooses to look for it, and that the complimentary remark recently made respecting this Journal, that it is a dozen years in advance of its readers, must be taken *cum grano salis.* However that may be, we shall in the future, as in the past, do our best to justify the honourable trust confided to us. We conclude by wishing all our readers a fair measure of prosperity in the year upon which we have now entered.

"As half in shade and half in sun
This world along its path advances,
May that side the sun's upon
Be all that e'er shall meet their glances!"

THE SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A MEETING of the above Association will be held on Thursday Evening next, January 11, at 17, Bloomsbury Square, at eight o'clock, when a paper will be read by Mr. J. H. HUGILL, on "The Hieroglyphics or Signs, as used to decorate the Show Bottles of the Pharmacist."

MANCHESTER CHEMISTS' ASSOCIATION AND SCHOOL OF PHARMACY.

A COURSE of fifteen lectures on Botany, by Mr. LEO H. GRINDON, will be delivered at 225, Oxford Street, on Friday evenings, at 9 P.M., commencing on January 12th; fee 15*s*. Tickets and further particulars may be obtained of Mr. F. BADEN BENGER, Honorary Secretary, 7, Exchange Street, Manchester.

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL.

Wednesday, January 3, 1877.

MR. JOHN WILLIAMS, PRESIDENT.

MR. WILLIAM DAWSON SAVAGE, VICE-PRESIDENT.

Present—Messrs. Atkins, Betty, Cracknell, Greenish, Hampson, Hanbury, Hills, Owen, Robbins, Sandford Shaw and Stacey.

The minutes of the previous meeting were read and confirmed.

Mr. HILLS said he had received a note from Messrs. Macmillan saying that the copies of the 'Pharmacographia' and 'Science Papers' presented by Mr. Thomas Hanbury were ready for delivery, and the Secretary was requested to arrange for their reception immediately.

The following being duly registered as Pharmaceutical Chemists were respectively granted a diploma stamped with the seal of the Society:—

Andrews, William Leatham.
Davidson, Alexander.
Frank, John.
Gostling, William Ayton.
Hart, Philip.
Hatch, James Oliver.
Robinson, Thomas Dexter.
Wilkinson-Newsholme, George Thomas.

ELECTIONS.

MEMBERS.

Pharmaceutical Chemists.

Andrews, William Leatham	Aldborough.
Frank, John	Whitby.
Gostling, William Ayton	Diss.
Hart, Philip	Bolton.
Hatch, James Oliver	Lancaster.
Helmore, William Holloway	Horsham.
Hicks, William Thomas	Bury St. Edmunds.
Jones, William Ellis	London.

Chemists and Druggists.

Dunkerley, James	London.
Probyn, Clifford	London.
Sinclair, James	Llandudno.
Thomas, Edwin Richard	Dowlais.

ASSOCIATES IN BUSINESS.

The following having passed their respective examinations, and being in business on their own account, were elected "Associates in Business" of the Society:—

Minor.

Bell, John Armour ....Greenock.
Blackbourn, Arthur..............Birmingham.
Dester, Joseph..................Bingham.
Frost, John ....Birmingham.
Gimblett, Washington............Ryde.
Hogg, James Edmund..............Worcester.
Jenkins, Thomas ....Aberystwith.
Loadman, James ....Southport.
Peel, Alfred ....Herne Hill.
Willan, William ....Preston.
Windle, John Thomas.............Chesterfield.

Modified.

Parker, William George ....Newcastle-on-Tyne.
Steward, John Alfred ....Worcester.
Wilkinson, William..............Chesterfield.
Williams, John..................Ruabon.

ASSOCIATES.

The following having passed their respective examinations, and having severally tendered the subscription for the current year, were elected "Associates" of the Society:—

Minor.

Alcock, Henry ....Coventry.
Anderson, James Johnstone ...Epworth.
Armistead, Hugh Baldwin ......Liverpool.
Asher, James ....Derby.
Barrow, Frank Arthur ....Newmarket.
Blaine, Thomas James Stewart..Hawick.
Cæsar, Julius...................Cosham.
Cooley, Walter Bromley ....Wolverhampton.
Curtis, Frederick George.........Dorchester.
Fraser, Alexander................Liverpool.
Glover, William Kensit ....Aberdeen.
Greenish, Henry George..........London.
Halhead, John Armstead ......Kirkby Lonsdale.
Hill, Francis ....Horncastle.
Hughes, Benjamin Longmore...Chichester.
Lincoln, William ....Ely.
McAlley, Robert ....Edinburgh.
Manduell, Thomas ....Hindpool.
Oldham, William ....Peterborough.
Piper, Walter George ....Norwich.
Presslie, Robert Dowell ....Aberdeen.
Tharle, Charles Albert...........Ventnor.
Thornber, William ....Preston.
Webb, William James.............Melbourn.

Modified.

Coates, George ....York.
Inkley, Jesse.....................Holbeach.
Johnstone, Robert ....Langholm.
Macewan, William Morrison ...London.
Morton, Samuel Edward.........Newington.
Ritchie, A. Wemyss..............Glasgow.
Sutton, William Denny ....Norwich.

APPRENTICES OR STUDENTS.

The following having passed the Preliminary Examination, and severally tendered the subscription for the current year, were elected "Apprentices or Students" of the Society:—

Akers, John ....Leighton Buzzard.
Atkins, William Ralph ....Salisbury.
Austin, Alfred ....Birmingham.
Berrill, Robert Andrew ....Doncaster.
Bloodworth, Thomas ....Bourne.
Bousfield, William ....Hull.
Brawn, James Ward ....Birmingham.
Carter, Henry Ayling............Winchester.
Cook, James ....South Molton.
Crowther, William Charles......Tickhill.
Dady, William ....Holt.
Dyer, Sydney Reginald ....Chiswick.
Eaton, Edward Jarrett ....Diss.
Evans, Richard....................Dinas Mawddwy.
Fentiman, Charles Henry ......London.
Firman, John William. ....Boston.
France, James Mead ....London.
Fraser, Alexander ....Edinburgh.
Graham, Andrew Ward .. ..Brighton.
Herbert, Henry Seaton ....Thorparch.
Hill, Arthur ....Cheltenham.
Homes, Joseph Peter ....Dudley.
Hughes, Edward ....Sarn.
Laing, James......................Brechin.
Lane, Thomas Jesse..............Barnstaple.
McCrindel, Thomas ... .Northampton.
Mantell, Charles, jun. ....Birmingham.
Matthews, Charles William ...London.
Pattinson, William ....Hexham.
Pearson, Henry ....Banbury.
Power, William ....Greenwich.
Ramsey, David R. ....Dundee.
Rees, Samuel......................Llandyssul.
Shacklock, James Harvey ......South Cave.
Skelton, John Hardy ....Gainsborough.
Stableforth, John William ..... London.
Stevens, Robert ....Bristol.
Stott, Walter Henry ....Wednesbury.
Swindells, Thomas ... .Manchester.
Tatam, Saml. Blackmore Chas...Ottery St. Mary.
Taylor, Solomon ....Stafford.
Trezise, William Augustus.... Sheffield.
Turnell, Tom ....Portland.
Tyndall, Francis ....Newcastle.
Tyson, Thomas Balmforth ......London.
Underwood, Charles Joseph ...Chatham.
Watts, John Manning............London.
Whigham, Robert Laing.. ......Cardigan.
Wilson, Samuel ....Hanley.
Woolliscroft, Henry..............Wrexham.

Several individuals were restored to their former status in the Society upon payment of the current year's subscription and a fine.

THE PHARMACY ACT.

Mr. HAMPSON, in accordance with notice, moved as follows:—

"In anticipation of an opportunity that may arise during the next session of Parliament of amending the Pharmacy Act of 1868, in any particular or particulars that the experience of its working may have proved necessary, it is desirable that a small Committee shall give the subject its best consideration, and report in due course to the Law and Parliamentary Committee, suggesting the amendment or amendments it deems important."

He said he considered it very important to take some such step, for the following reasons: An opportunity might arise in the ensuing session which could be utilized for an amendment of the Act of 1868, and it was very desirable that the Council should be prepared with such amendments as it might think necessary; another consideration, of still greater importance, was that the Act of 1868 in one or two important respects had proved a failure, and the Council had hesitated to test its strength, fearing it might prove too feeble to bear the tension of a trial at law. The Act was really a dead letter so far as it affected the action of public companies, who had ridden rough shod through its most important provisions. Hence the law could only be put in operation when it affected individuals, and the result was that such action appeared both tyrannical and unjust.

Mr. HILLS suggested that the Council should go into committee to discuss this question.

Mr. HAMPSON said he saw no necessity for so doing, and he should object to the deliberations on this subject being withheld from the knowledge of the members at large. He was not casting any reflections on the Council, but a duty and responsibility rested on it, it being the administrative body selected by the State to carry out the law. For several years past certain conditions had arisen by which the spirit of the Act was totally ignored, and great and growing injury resulted to those who felt bound to adhere faithfully to its provisions. The Council ought, therefore, to look about to see the best way of getting out of this difficulty. If the motion were carried it would be possible to utilize any opportunity which might arise in Parliament, but if not, he thought the Council ought itself to make an opportunity, and after laying the grave statement of their position before the Government, ask its assistance in amending the law. If the spirit of the Act of 1868 were the right one it seemed to him there was no other course to pursue except one of negligence and disregard of what was believed to be right and equitable. The Council should not act as if the law had given chemists and druggists privileges which would not bear the light of public discussion, and if need be controversy too, and the course he proposed seemed to him only consistent with common courage and a determination to maintain the privileges given by the Act. Besides these main considerations there were others worthy of attention, such as the difficulty frequently experienced in finding the real owner of a business, and there were no doubt other minor improvements which a Committee could suggest. He believed the Society had arrived at a crisis in its history, but if the Council acted with firmness and determination it would get rid of the besetting difficulties and give great satisfaction to its members and to the trade.

Mr. GREENISH seconded the motion.

Mr. ATKINS asked if the intention was to go to the House of Commons for a new Act of Parliament.

The PRESIDENT said he understood that was the desire of Mr. Hampson, if an opportunity did not arise of obtaining the alterations desired in connection with some other Act.

Mr. ATKINS thought such a step required very careful consideration. It would open up the whole question of pharmaceutical legislation again, and lead to warm discussions which might not be at all advantageous. He was rather astonished to find Mr. Hampson bringing this forward, seeing that another movement had recently been set on foot, to which he had lent his influence, the object of which was to supplement what was done at the Council Board. Surely that body need not exist if it were necessary to come back to the Council for what was required. Did he understand Mr. Hampson to say that the Council had neglected its duties?

Mr. HAMPSON said he had remarked that such a charge might be made if it did not take some action.

Mr. ATKINS said he had come to the Council under the impression that it had endeavoured to do its very utmost with regard to the question to which Mr. Hampson had alluded, and which might as well be openly named—co-operative stores; and he still remained of the same opinion, that the Council had done its very best to deal with that important matter in the best interests of pharmacy generally. He was very glad, therefore, to hear from Mr. Hampson that he did not charge the Council with any neglect of duty in the past; but he still thought the matter should be carefully considered before going to Parliament for another Act.

Mr. SANDFORD thought Mr. Hampson must have forgotten that there was a Parliamentary Committee which was always ready to take advantage of any opportunity that arose for promoting the interests of the Society, and that Committee could be put in action at any moment. There were also a President and Vice-President who were never found lacking, and a Secretary who was always on the watch for anything which affected the interests of the Society. It therefore seemed like casting a slur on that Committee to appoint another one for this specific purpose. The Committee could be summoned at any time, and whenever any active business was going on a section of the Committee was able to meet and do what this smaller proposed committee was intended to do. Mr. Hampson said the Act was a failure with regard to public companies, and spoke of the spirit of the Act not being carried out, but he must say that the spirit of it was first and foremost that the public should be protected against the mistakes made by unqualified persons, and so far as public companies and co-operative stores were concerned, it might be said that so long as they employed qualified and registered men, the public safety was not endangered. He did not uphold co-operative stores, which he thought were doing an immense deal of mischief, but they should be opposed on broader grounds than this. The Pharmacy Act was passed to secure the public safety, and from that sprang certain advantages to chemists and druggists in Great Britain; but if it were attempted to put the interests of chemists and druggists before those of the public, discredit would be thrown upon the Act, and if the Council went to Parliament on that ground it would not receive much support. Co-operative stores had taken a great hold of public opinion, and even of the members of the House of Commons, and if an attempt were made to prevent public companies trading as chemists and druggists, Parliament would say, "You are only thinking of your own private interests, and we will rather pass an Act to enable companies to carry on business." With regard to the ownership of businesses that was a separate question; there had been more than one attempt to pass a measure for the registration of all firms, and the Council should try to assist any such general measure rather than seek a special Act, affecting only one business. He had certainly understood Mr. Hampson to say that the Council had neglected its duty in not prosecuting co-operative stores, but it had taken the best legal advice upon the question, and had decided over and over again not to take any action in the matter. He was also surprised to hear it said that the Council had acted tyrannically in putting the Act in force against individuals, and he should like Mr. Hampson to bring forward a single instance in which it had acted tyrannically. It appeared to him that the appointment of such a committee as was proposed was utterly needless, and he should therefore oppose the motion.

Mr. SHAW supported the motion. He did not understand it as expressing an intention to go to Parliament for a special Act, but that if fresh legislation were attempted the Council must be in a position to suggest such amendments as might seem desirable. It was stated some months ago that Lord Sandon intended to bring in a Bill with regard to patent medicines, which was a matter of great importance to the whole trade. It seemed most anomalous that an Act of Parliament should be passed to secure the lives and health of the community by requiring all chemists and druggists to pass an examination before they could sell a pennyworth of certain poisonous articles, and yet any of these scheduled poisons might be sold with impunity if they bore a patent medicine stamp. Then there was the question of making addition to the schedule of poisons, and it was said that Sir William Frazer intended to bring in a measure on the subject. If he did it would be quite as well that the Council should be prepared for it, and not have to decide in a hurry upon any points which must be raised. The resolution could do no harm, and might be of material service.

Mr. OWEN suggested that the Parliamentary Committee might be instructed to do what was required.

The PRESIDENT remarked that the Parliamentary Committee had power to appoint a sub-committee for the purpose, if necessary, but the Council required no fresh Act of Parliament or increased powers, to add to the Schedule of Poisons; it was simply a question of expedience.

Mr. OWEN said there did not seem anything to be done. He thought the Council should wait and see what was proposed, unless it was prepared to apply for a new Act.

Mr. HILLS could not see that a new act was required. It was better to "bear those ills we have than fly to others that we know not of." He would much rather wait and watch events than bring in a new bill.

Mr. CRACKNELL agreed in this view. The proposition seemed to him an aimless one.

Mr. ATKINS thought the only ground on which the motion could be supported was that the Parliamentary Committee had seriously failed in its duties. The attitude of the Council in his view ought to be one of strict supervision of what was being done in Parliament, but that was very different to proposing amendments.

Mr. BETTY could not agree with those who thought there was nothing to be done but follow the old routine manner of conducting the Society's business. He was not surprised that the motion did not receive much present support from Mr. Sandford, because those who had taken an active part in passing a great public measure were very often disposed to rest on their laurels, and feel that nothing more remained to be done; but at the same time he felt sure that when the Society did come to measure its strength with public opinion, or with existing interests, Mr. Sandford would give the Council his valuable aid and advice, whether it went for a new act or simply to amend one introduced independently. For his own part he saw no reason why the Society should fear the result of public discussion on the nature of their duties and their consequent position. Looking to the high examinations which chemists and druggists were now compelled to pass, it must be acknowledged that they really deserved a professional status, and he believed the public would view it in that light, and willingly accord them the same privileges which were given to other professional bodies. Unless there were some tangible grounds for going to Parliament it would be reckless to challenge public opinion, however confident that it would be pronounced in their favour; but the Society had now had eight years' experience of the working of the Act, and that might be considered a fair average of the life of an unamended Act of Parliament, which they were fully conscious was to some extent incomplete in its original scope, and as affected by subsequent legislation. If a Committee were given time to make a report, every defect might be brought forward. He hoped that any idea of a slur on the Parliamentary Committee would be removed by Mr. Hampson modifying the motion and asking that Committee to take the matter into consideration. In the opinion of many one very important point was the introduction of the word "pharmaceutical chemist" into the Irish Act, as a result of which Irish pharmacists might come to England and assume that title, and the Society would thus lose the exclusive right to it. It was said that if the Act were meddled with no one could tell what might be the end of it, but he did not believe that the privileges of the trade, small as they were, hung by so fragile a thread that a mere breath would blow them away. If the Council could not go to Parliament resting on the justice of its cause, it was in a false position altogether and the sooner the Board of Examiners was abolished and chemists and druggists returned to the position of ordinary shopkeepers the better. As it was the general wish of the pharmaceutical body to amend the Pharmacy Act of 1868, the opinion of Parliament should be taken, and if they were beaten on some points they would know their position, and bear it like men. He should therefore support the motion of Mr. Hampson.

Mr. HAMPSON said he moved this simply as a preliminary step.

Mr. ATKINS thought every purpose would be answered if the Parliamentary Committee were instructed to be strictly watchful with regard to future legislation.

The PRESIDENT remarked that when the Parliamentary Committee met its time was pretty well occupied with questions of detail, and no time remained for discussing general principles, therefore it might be as well if a sub-committee were appointed.

Mr. SANDFORD said he believed such matters as had been now brought forward had always been carefully considered when necessary. The question of co-operative stores had been discussed by the Committee again and again.

Mr. ROBBINS said the Council seemed to be discussing a question not raised in the motion, viz., whether it should go to Parliament at all.

Mr. STACEY said he could not understand the motion. On the face of it, it was simply a vote of censure on the Parliamentary Committee; but, from Mr. Hampson's opening remarks, he found that there was something much deeper in it than anyone could discover at first sight. It was, in fact, a stepping-stone to an amendment of the present Act, and for introducing fresh powers; and he regretted that this object had not been brought plainly and openly before the Council. The Council had wandered off into proposed amendments of the Pharmacy Act, a subject which was not before it, and which would come before it much better in the form of a report from the Committee. The Committee was a very efficient one, and was competent at any time to appoint a sub-committee to look into any particular subject which might arise. Such a sub-committee might be appointed, if necessary, to go through the Act carefully, and submit any amendment which might be deemed desirable to the Committee, which would then report to the Council. That would be a straightforward course; but he thought the passing of the present motion would be derogatory to the Council. He would not go *seriatim* through Mr. Hampson's remarks, some of which he regretted; but he must say, from his short experience at the Council and on Committees, that he was convinced no men could be found who had more at heart the interests of the whole body of chemists and druggists throughout Great Britain.

Mr. HAMPSON in reply said he had listened very carefully to the remarks of his friends, some of whom supposed that he had intended to cast a censure upon them; but that was entirely foreign to his intention. He did not think the step he had taken was an injudicious one in any way. His view was that the Committee proposed, after deliberate and careful discussion of the Pharmacy Act and its working, would be better prepared to go into the whole question and do justice to it than a large Committee. He wished the Council to be fully possessed of all the facts, and be prepared to utilize any attempt at fresh legislation. That was his primary object, but he did maintain that if the Council did not take the requisite steps to amend the Pharmacy Act it would, nevertheless, have to be amended in a very short time. He had been obliged to allude to various defects in the Act, and naturally he had referred to the question of public companies usurping the functions of registered chemists and druggists, and he was astonished to hear Mr. Sandford say that the Act was not in any way a failure, and that the spirit of it was not infringed. What he referred to when he said that they had been carrying out the Act in an apparently tyrannical manner, was that it had been administered partially, and not impartially. He looked first to the public good, and had that mainly in view, and he maintained still that the Council would be neglecting its duty if the Pharmacy Act were not carried out according to its spirit and intention; and this was not now done in certain cases. The Act was a failure in this respect that it punished a man who opened a shop without a qualification, but permitted a public company to do the same without a qualification. To remedy this, together with other defects, he proposed the appointment of this Committee, not from any disrespect to the Parliamentary Committee, but as an assistance to it.

Mr. ATKINS moved and Mr. OWEN seconded the following amendment:—

"That the Parliamentary Committee be requested to appoint a small sub-committee to consider the provisions of the Pharmacy Act, 1868, with a view of preparing or suggesting any alterations which it may deem expedient, and to report to the Law and Parliamentary Committee thereon."

Mr. HAMPSON said he was quite willing to accept the amendment and would withdraw his motion.

Mr. SANDFORD said this carried the thing much further than the original motion, because it assumed that there were certain amendments required in the Act. He had never said that the Pharmacy Act was perfect or could not be amended, but he did not think it worth while to pass such a motion as an abstract principle.

After some further conversation, Mr. SANDFORD moved an amendment in the following form :—

"That the Parliamentary Committee be requested to appoint a sub-committee to watch any opportunities that may arise during the next session of Parliament of amending the Pharmacy Act, 1868, in any particular or particulars that the experience of its working may have proved necessary, or of supplying any deficiency therein through other proposed acts, and to report in due course to the Parliamentary Committee."

The VICE-PRESIDENT seconded this amendment, and upon a division being taken, the following voted :—

For.—Cracknell, Hills, Sandford, Savage.

Against.—Atkins, Betty, Greenish, Hampson, Owen, Robbins, Shaw, Stacey.

The President was present but did not vote.

Mr. Hanbury was not present at the division.

The motion proposed by Mr. Atkins was then put, and carried by the same majority.

REPORTS OF COMMITTEES.

FINANCE.

The report of this Committee was read and adopted, and various accounts ordered to be paid.

It was also unanimously resolved that the salary of the Curator be raised to £200 per annum.

BENEVOLENT FUND.

The report of this Committee included a recommendation of the following grant:—

Twenty guineas to the widow of a former member (to the date of his death), having three children dependent upon her. The money to be placed in Mr. Owen's hands for the purpose of assisting to secure the election of one of the children into the British Orphan Asylum, if he saw there was an opportunity of doing so.

A letter had been received from the Treasurer of the late Norwich Chemists' Association, inclosing a cheque for £10 17*s*., being the balance left in his hands on winding up the affairs of the association, which amount it had been resolved should be handed to the Benevolent Fund of the Pharmaceutical Society.

The report and recommendation of the Committee were received and adopted.

Mr. GREENISH said he was very glad as a member of the Benevolent Fund Committee to receive the £10 17*s*. from Norwich, but he could not help expressing his regret that the means of education afforded in Norwich had not been appreciated by the young men there. To see such a collapse was to his mind more grievous than any pleasure he derived from the receipt of the money.

The PRESIDENT was very glad that Mr. Greenish had called attentiou to this circumstance, for this money must be received with mingled feelings. It was certainly a great misfortune that local associations, like that at Norwich, were not better supported.

The Secretary reported that a registered chemist and druggist who had received two grants from the Fund, having just been elected into the Charterhouse, had called on him, and from the first money received from that institution, had given half-a-guinea as an annual subscription to the Fund.

HOUSE.

The Committee had considered several matters connected with the museum, lecture, and laboratory arrangements, including the fitting up of the octagon laboratory, for examination purposes, the consideration of which was adjourned.

The PRESIDENT said he had been looking into this matter, and, with the consent of the Council, was willing to superintend the rearrangement of the octagon laboratory, so as to fit it properly for the chemical examinations.

The report was received, and the President was requested to carry out the desired alterations.

Mr. GREENISH spoke to the need for such rearrangements, which he had frequently noticed.

LIBRARY, MUSEUM AND LABORATORY.

This report stated that communications had taken place with the printers with regard to defects in cutting the edges of the Journal, and the steps which were recommended to prevent this in future.

The Librarian had reported that the average attendance during the preceding month had been during the day 24 ; evening 8. The circulation of books had been 175 in town, 37 in the country. Several duplicate sets of periodicals being found in the Library, it was suggested that, if acceptable, they should be sent to the library of the North British Branch.

The following books were recommended for purchase:—

'Indexes to the Annales de Chimie et de Physique 1836 to 1850.'

Baillon's 'Dictionnaire de Botanique.'

Cooke's 'Mycographia.'

A case of foreign periodicals had been received from Messrs. Friedlander, of Berlin.

A letter had been received from Professor Balfour, of Edinburgh, stating that there were certain deficiencies in the sets of the *Pharmaceutical Journal* in the Government Library attached to the Botanic Gardens, and asking if they could be supplied. It was recommended that the missing copies should be sent, as it had been ascertained this could be done.

The Curator had reported the attendance in the museum as being on the average, morning 17, evening 3. He also reported the progress which had been made in the preparation of the catalogue and in the arrangement of the Hanbury collection. An application had been received for the loan of some specimens from the museum to exhibit at a soirée at St. Thomas's Hospital, which the Committee had granted. Professor Attfield reported that he had 52 entries since the commencement of the session, 45 being now at work, also that the attendance of the Bell Scholars during the month had been regular.

The report and recommendations were received and adopted.

Mr. GREENISH drew attention to the pleasing fact that the circulation of books in the country was constantly increasing.

LAW AND PARLIAMENTARY.

The report of this Committee included details of the steps taken in connection with several cases of alleged breaches of the Pharmacy Act. The report was adopted.

THE EXAMINATIONS.

The PRESIDENT drew attention to the practice, which was on the increase, of young men sending in their names and paying fees for examination at a certain date, and withdrawing at the last moment. This was not fair to the Society or to the Examiners, and it was, therefore proposed that in future, a portion of the fee should be forfeited, as in the case of an unsuccessful candidate, except in the case of sudden illness.

Mr. Greenish thought every consideration should be shown to the young men coming up for the Minor Examination, and that only a small sum at any rate should be forfeited in case of withdrawal.

The Vice-President suggested that the matter should be adjourned till next month, in order to give time for further consideration. In some cases the fault might not be at all in the young men themselves, but in their employers.

The matter was ultimately referred to the Library, Museum, and Laboratory Committee.

Report of Examinations in December, 1876.

ENGLAND AND WALES.

Mr. Hampson asked if the Secretary could give any information with regard to the statement contained in the following paragraph, which appeared in the *Echo* of the previous day.

"Miss Wren Hoskyns has very recently offered to place at the disposal of the Pharmaceutical Society or the Apothecaries' Hall a scholarship for young ladies qualifying for the profession of practical chemist and the general dispensing of medicines. The Society has declined the trusteeship, though there are yet hopes that the scholarship may be recognized."

The Secretary said he had heard nothing of any such application.

Parliamentary and Law Proceedings.

Poisoning by Opium Pills.

On Friday, December 30, Dr. Diplock, the coroner for West Middlesex, resumed the adjourned inquiry into the circumstances attending the death of Henry Randall, barman, at Chelsea, who is alleged to have died from the effects of opium poisoning. The deceased man was on intimate terms with Jeanette Dutten, one of the nurses at the Hospital for Women and Children in the King's Road, Chelsea, who gave him some pills containing opium, which she admitted having abstracted from a box in the surgery at the hospital. Deceased swallowed four of the pills to cure a cough, and in a couple of hours died. At the opening of the inquiry the girl was called, and, after being cautioned by the coroner, elected to be sworn, and admitted having stolen the pills and given them to the deceased, but strongly denied any criminal intent. She declared, also, that she could not read or write, and therefore did not notice the label "Opium" upon the box from which she abstracted the pills.

Dr. John Leonard stated that he had made a *post-mortem* examination of the body of deceased, and found that there were no external marks of violence. The body was well nourished, the head and neck were congested, and the substance of the brain and the pia mater were intensely engorged with blood. The brain itself was softened, and there was slight effusion at the base and into the ventricles of the brain. The stomach was healthy, and contained about 6 ozs. of a thick fluid, in which a suitable test indicated the presence of morphia.

Miss Myddleton, barmaid, said that she remembered seeing the deceased take some pills on Monday, the 18th instant. He offered some of them to witness and another person, saying they had been given to him. He did not say what they were for. Saw him put four of them into his mouth, but whether he swallowed them she could not say. That was about nine o'clock on the Monday night, shortly before he had his supper. He gave some of them to witness, who threw them over the bar. Did not know if anyone else took any of the pills. He said that one of the girls at the hospital had given them to him.

Clara Handsley, a nurse at the Hospital for Women and Children, deposed that she gave Jeanette Dutten some pills for a cough some time back. They were the ordinary cough pills, and were ordered to be given by the matron.

The Coroner: Were those pills the same size as those now produced? (the opium pills found on the deceased and in the box labelled "Opium" taken from the surgery).

Witness: No; they were larger, but not much larger.

Coroner: Could Dutten write?—Witness: I can't say. I never saw her do so, but the cook may have written for her. I never did.

By Mr. Abrams: Dutten saw where I took the pills from. The dispensary was open to any one to go there and take the poisons, etc., but the servants were not supposed to go into the dispensary without orders. We keep all sorts of pills in small quantities in our cupboards to give to the patients when ordered. The pills are kept in bottles, which are labelled. I know that the opium pills are given to the patients to soothe them, one pill being a dose.

Dr. Leonard, in answer to a juror, said that his experience had shown him that all poisons were kept under lock and key in the majority of London hospitals, so that an accident of this kind could hardly happen. The overdose of opium pills had no doubt caused the death.

The Coroner, in summing up the case to the jury, said it was well known that any person might administer a potion to another, provided that potion was a harmless one, without offending the law; but the case in question was very different. Lord Lyndhurst had laid down the law that if any person were killed through the negligence, carelessnes, recklessness, or heedlessness of another party, the latter was guilty of manslaughter, and it would be the duty of the jury to return a verdict of manslaughter against Jeannette Dutten, and leave a higher court to settle the matter.

The jury deliberated and returned the following verdict: "That the deceased died on the 19th inst. from the effects of poisoning by opium given to him by one Jeannette Dutten; that the said Jeannette Dutten has been guilty of great indiscretion and negligence, and that the hospital authorities had also been guilty of great negligence in leaving the poisons, etc., in a room accessible to any ignorant person who chose to go there and steal the deadly drugs lying in the room."—The girl was then called before the jury and severely reprimanded by the coroner who said that if the jury had acted up to the strict letter of the law they would have sent her to take her trial for the manslaughter of the deceased.

Poisoning by Cyanide of Potassium.

Dr. Danford Thomas held an inquest on Saturday, December 31, in St. Pancras, as to the death of Henry Boulter, aged 23. The evidence showed that deceased, in his wife's presence, took a bottle from his pocket containing cyanide of potassium, and placing it to his mouth took a dose. He never spoke again, and died in ten minutes afterwards. Deceased purchased the cyanide of potassium in Seven Dials on the previous evening, and showing it to one of his friends, said they would never meet more, as the stuff in the bottle was poison. A relative of deceased said there was a suicidal tendency in the family, two of his brothers having attempted to commit suicide. She believed the insanity was brought on by drink, both father and sons being much given to intemperance.—Verdict, Suicide whilst in a state of unsound mind, brought on by excessive drinking.

Obituary.

Notice has been received of the deaths of the following:—

On the 2nd October, 1876, Mr. George Garmeson Bradbury, Chemist and Druggist, Shavington, Nantwich. Aged 62 years.

On the 24th of October, 1876, Mr. Thomas Haugh, Chemist and Druggist, Brampton, Cumberland. Aged 83 years.

On the 2nd of December, 1876, Mr. Alfred Harris, Chemist and Druggist, South Norwood. Aged 42 years.

On the 13th December, 1876, Mr. William Hartley, Pharmaceutical Chemist, St. Stephen's Crescent, Kennington. Mr. Hartley had been a Member of the Pharmaceutical Society since 1863.

On the 16th of December, 1876, Mr. Philip Bright, Chemist and Druggist, Brecon.

Correspondence.

Chrysophanic Acid Ointment.

Sir,—Remembering the old saying "better late than never," I thought, as I have had a good deal to do with this chrysophanic acid business, that a word or two from me, might not be altogether out of place. Especially so since I had the pleasure of manufacturing the chrysophanic acid which afterwards formed the subject of Mr. Balmanno Squire's very interesting and excellent paper, according to the process devised by Professor Attfield.

I am sorry I cannot concur in the recommendation expressed by Mr. Squire, that benzole should be used in its preparation pharmaceutically to form an ointment; moreover I am quite of the opinion expressed by Mr. Gerrard, that a very excellent ointment may be prepared by dissolving the acid in hot fat, and then transferring it to a mortar and rubbing it down until cold.

If to an ointment so prepared three or four drops per ounce of otto of roses is added a most beautiful preparation results, possessing in an eminent degree all the active properties of the acid with the delicate and attractive odour of the rose.

In conclusion, I would take this opportunity of stating, with regard to the investigation of Goa powder therapeutically, that Dr. Ashburton Thompson has pushed the matter even further, and has been giving to his patients Goa powder and chrysophanic acid to take internally, as well as for use externally, and his research forms the subject of a paper to be read before the Harveian Society on the 18th proximo, when it is hoped an increased amount of information will be brought out and contributed.

The last link for investigation on this subject appears to depend upon the growth of a plant in the Royal Botanic Gardens, Edinburgh, from which it is believed the whole thing emanates. I had the pleasure of making the acquaintance of this little plant in the summer of 1875, through the kindness of Mr. M'Nab—and it was then about 16 inches in height, in a flower pot, and kept in the house containing tropical plants. I am glad to learn from a paper in the *Medical Times and Gazette*, that it is still growing on, as it will be an interesting question for botanists ultimately to determine.

A. W. Postans.

35, Baker Street, W.

Chemists and Druggists and the Medical Acts.

Sir,—The thanks of your readers are due to Mr. Fryer, for his letter in the *Pharmaceutical Journal* last week, as indicating a want of more light upon the subject, which probably arises from the fact that many of the sections of the various Acts were read at the meeting referred to, and for the sake of brevity not included in the report. For the guidance of those interested, I will explain a little more fully my views of the meaning of the Acts, and in doing so, I presume your correspondent will admit that in reading an Act of Parliament the words therein used must be interpreted according to their literal meaning at the time the Act was written.

The 5th section of the Apothecaries' Act, 1815, reads thus:—"And whereas it is the duty of every person using or exercising the art and mystery of an apothecary, to prepare with exactness and to dispense such medicines as may be directed for the sick by any physician lawfully licensed to practise physic by the President and Commonalty of the Faculty of Physic in London, or by either of the two Universities of Oxford and Cambridge: Therefore, for the further pretection, security, and benefit of His Majesty's subjects, and for the better regulation of the practice of physic throughout England and Wales be it enacted, That if any person using or exercising the art and mystery of an apothecary shall at any time knowingly, wilfully, and contumaciously refuse to make, mix, compound, prepare, give, apply, or administer, or in any way to sell, set on sale, put forth, or put to sale, to any person or persons whatever, any medicines, compound medicines or medicinable," etc.

It seems evident that when this Act was written the only person properly qualified to treat sick people was the physician who was lawfully licensed to carry on the practice of physic. Had it been otherwise we should, in some section of the Act, have discovered the duty of the apothecary, other than that of keeping a shop for the supply of the medicines ordered by the physician; and although the words "science and practice of medicine" do occur in the 14th section, yet if these words are taken in conjunction with the words which precede and follow after, they do not give the apothecary the right to practise medicine—to do so would have raised him at once to the position of the physician,—but merely show that one of the qualifications necessary for a person to have who wished to be registered as an apothecary was a knowledge of medicine, so far as it applied to his business, such, for instance, as pharmacology, and I am inclined to the belief that the word "medicine" in this section, should be read (according to modern language) "pharmacy." There is no definition of the business or profession of an apothecary, except that given in the 5th section previously referred to.

Your correspondent will be surprised to find that in the case of the *Apothecaries' Society* v. *Nottingham*, the decision of Baron Bramwell is considered good. Why? Because the chemist and druggist assumed the title of a properly registered medical practitioner.

E. Yewdall.

Leeds, Jan. 1877.

Communications, Letters, etc., have been received from Mr. Dyson, Dr. Brown, Mr. Crow, Mr. Yewdall, Mr. Benger, Mr. Bennett, Dr. Bond, Dr. Griffiths.

THE SPECTROSCOPE IN PHARMACY.

BY WILLIAM GILMOUR.

(*Continued from page* 531.)

In examining the various officinal extracts and tinctures for the chlorophyll spectrum, the consideration of the general form and appearance in which the solutions will be presented to us is not unimportant. A tincture for example, or the solution of an extract (in every instance a spirituous or watery solution, as the case may be), contains more colouring matter, it will be kept in mind, than that imparted by the mere presence of the chlorophyll. This tends to mask the spectra very materially; indeed, so much so that few, if any, of the tinctures can be examined even in very minute volume in their natural state, whilst in the case of the extracts the dilution requires to be carried to such an extent as altogether to fatally injure the nature of the spectra. This, it will at once be understood, prevents not only a proper observation of individual solutions where the chlorophyll may happen to be present only in minute quantity, but probably what is equally, if not more important still, it prevents a proper comparison being made between spectra of different solutions. In other words, the solution containing the largest percentage of foreign colouring-matter may contain the smallest percentage of chlorophyll, so that there would necessarily be, on the one hand, unequal degrees of dilution, or on the other unequal depths of colour in making any comparison. Uniform results would, therefore, be unattainable under either condition. In these circumstances if the chlorophyll can be extracted from the preparation and presented to the spectroscope as a pure solution, without the addition of any foreign colouring-matter, investigation will be much facilitated and many other important results gained. There are several substances which may be employed to effect this purpose, but probably none possess all the advantages of benzole. It may be mixed, for example, with almost every Pharmacopœia tincture containing chlorophyll, and in a short time it will be found again to separate, containing nearly all the chlorophyll in solution. Comparison may thus very readily be made between spectra of different samples of the same tincture as well as of tinctures from other substances. In cases where the relative intensities of different spectra are to be compared, a very good plan is to take given volumes of the tinctures to be examined and place them in different test tubes of similar diameter and add to them equal quantities of benzole. An examination made in this way gives a very good approximation of the amount of chlorophyll held in solution by the respective tinctures. If the tincture examined, say, be digitalis, the benzole chlorophyll solution will be of a beautiful dark olive-green, which will contain, if it be recently made from leaves carefully collected, dried, and preserved as previously explained, five bands of the appearance and situated as follows: namely, I., a band very dark and of considerable breadth, immediately behind B; II., a second between C and D, dark, but of no great breadth; III., a third behind D, very delicate and only appearing in very recent preparations;* IV., a fourth a little further behind D., and V., a fifth before E. These last two are of some considerable breadth, but are also very delicate and are therefore frequently not met with, having undergone decomposition from some of the causes already referred to. Various circumstances may modify individual spectra, but as a rule the appearance of these different bands give a very good indication of the history, condition, and, to some extent, therapeutic value of the preparation examined. It very rarely happens that band I. is of very marked intensity and breadth without one or more of the other bands also being present, and more seldom still that it is to any degree attenuated without being to some extent of therapeutic significance.

The extracts require to be manipulated in a way slightly different from the foregoing to suit their special peculiarities. Chlorophyll being only sparingly soluble in water (it is generally believed to be insoluble, but this is not the case as a watery infusion of any of the leaves mentioned will give a decided spectrum), a tincture may be made by adding spirit to the extract previously dissolved in water, and afterwards allowing to stand for some time. This solution being filtered may be treated with benzole, as in the case of the tinctures, the chlorophyll dissolving out from the different extracts in various shades, from a light to a very dark emerald green. The only objections to this plan are that the process of maceration occupies some little time, and that some of the extracts do not readily yield up their chlorophyll under these circumstances to the spirit. Twenty-four hours' maceration gave very good results with some of the extracts, but lettuce failed to give any indication whatever of an absorption band when treated in the same way and for the same length of time, although the chlorophyll was afterwards proved to be present in considerable abundance. The better plan is, therefore, probably to make a solution of the extract in spirit and water, to which at once add the benzole and mix thoroughly. Owing to the coagulation of the gum present in the extract the benzole will separate again with some difficulty, but the application of a little heat will facilitate the separation, and sufficient may thus be obtained to yield a characteristic spectrum. Treated in this way, if the extracts are fresh and good, the benzole chlorophyll solution, unless unduly diluted will be of a beautiful dark olive green, but the appearance will vary as well as the spectra, especially of those extracts less commonly in use. I have come repeatedly across extracts without a vestige of an absorption band and many others very much attenuated, but the following have been picked out, not only from the spectra yielded by them being characteristic, but also from the fact that they were otherways known to be the best extracts out of many examined.

Extract. Aconiti.—Solution very light yellowish green; band I. dark but not broad; band II. faint; no other bands visible; a considerable amount of shading at violet end and spectrum not all absorbed until beyond the green. This extract, like most of the other extracts of aconite examined, was in several respects unsatisfactory. It was somewhat dry and tough, cutting, or rather breaking, with a brown fracture, and giving a brown mixture with water without any trace of green whatever. One hundred grains of the extract mixed with water and washed

* This band is sometimes classified as band V. It is here always referred to as band III., the order of its rotation.

till the filtrate ceased to give any colour yielded on drying over a vapour bath, 8 grains of a chlorophyllic residue which, on treating with benzole, gave a dark green solution whose spectrum corresponded in every respect with the foregoing, with the exception that there was less shading and the spectrum was all absorbed a little beyond the middle of the green.

Extract. Belladonnæ.—Solution very dark green; bands I. and II. united forming one dark very broad band with a faint trace of red shining through at a point intermediate betwixt the two bands; band III. faint; band IV. of some breadth but not very dark. All the spectrum was abruptly absorbed immediately beyond this so that band V. was not visible. On diluting the solution, bands I. and II. separated, band III. disappeared and band IV. decidedly thinned, whilst the spectrum became elongated, band V. being still invisible. This extract was of a good pilular consistence and on mixing with water gave the dark green hue characteristic of a fresh extract. One hundred grains mixed with water and washed till the filtrate passed through colourless yielded, on drying over a vapour bath, 20 grains of a dark green chlorophyllic residue which, on treating with benzole, gave a very dark olive-green solution with a spectrum even more decided than the original solution, with the exception that band III. was not visible and the absorption in the middle of the green was even more abrupt.

Extract. Conii.—Solution deep green; bands I. and II. united, with a shade of red intermediate betwixt the two bands; band III. very faint; band IV. quite distinct but of no great depth: all the spectrum absorbed immediately beyond this. On diluting the solution the same action took place as in the belladonna extract, which extract it also closely resembled in consistence and in general appearance, both in the dry state and mixed with water. One hundred grains of the extract washed and dried as in the previous extracts yielded 17½ grains of a dark green chlorophyllic residue, which treated with benzole gave a very dark yellowish green solution, the spectrum of which differed in several respects from the foregoing. The extreme red, for example, beyond the first dark band was the only part of the spectrum unchanged. Bands I. and II. were united in one very dark broad band. The orange of the spectrum was changed to a dirty green, and bands III. and IV., though not of themselves very decided, were united by a dark shading. On diluting the solution the action was the same as in previous instances, bands III. and IV., however, disappearing altogether: the shading in the orange changing and the colour of the spectrum gradually assuming its normal appearance.

Extract. Hyoscyami.—Solution deep green; band I. broad and dark, but not shading into band II. as in the conium. Band II. dark, but of no great breadth; band III. not present; band IV. distinct but not broad, and all absorbed towards extreme of green. One hundred grains treated as in the previous extracts yielded 24 grains of a light green chlorophyllic residue which with benzole gave a deep green solution resembling in every respect the first solution with the exception that band IV. was not present in the spectrum and complete absorption took place in the middle of the green.

Extract. Lactucæ.—Light green solution; band I. dark, but of no great breadth; band II. faint. No other bands present, but a considerable amount of shading at violet end of spectrum, and complete absorption only took place towards the middle of the blue. Treated as the other extracts one hundred grains yielded twenty-one grains of a light green chlorophyllic residue, which with benzole gave a dark green solution, the spectrum of which was much more decided than in its original solution. Bands I. and II., for example, were now united by a dark shading, and band IV. was visible though not very decided, whilst complete absorption took place in middle of the green. With all the foregoing extracts it should be noticed that when the respective solutions from the fresh extract, and from the washed and dried chlorophyllic residue of the same extract were of nearly equal density of shade, the spectra very closely approximated. In one respect only could there be said to be any marked difference betwixt them, namely, that in several instances band I. of the dried chlorophyll solution was more refracted than in the case of the simple solution. This alteration in the position of the band had no effect on its susceptibility to change, either on exposure or, so far as could be ascertained, on subjecting it to chemical action, and therefore we may conclude that, whatever its cause, it had less a therapeutic than a scientific interest and bearing.

Extract. Cannabis Indicæ.—This and the following extract differ from the foregoing in respect that they are to a certain extent alcoholic preparations, but as they both yield decided spectra, and as moreover, the cannabis indica at least is an important and powerful therapeutic agent, frequently subject to adulteration as well as alteration in its constituents, it is but proper to refer to them here. The cannabis indica will yield the same spectrum, either with alcohol or benzole, and four or five grains extract to the ounce will give a solution strong enough to show the different absorption bands present in it. If the solution be a deep green it will generally show band I., not very dark, but of some breadth, with a considerable shading towards the violet end; no other band probably being distinctly visible. Increasing the strength of the solution until the green deepens with transmitted light into a peculiar lurid brown, band I. will intensify somewhat, and a shading will at the same time take place towards band II., which is very faint, having only the appearance of a continuation of the shading. Band IV. will also show very faintly, and complete absorption will take place towards the end of the green.

Extract. Lupuli.—An aqueous solution of this extract, to which spirit had been added, gave with benzole (same as in the green extracts) a very light green solution, which showed band I. very faint. No other band visible, and all absorbed with a considerable amount of shading towards middle of blue. A fresh portion of extract washed and dried gave a dark resinous residue, which dissolved in benzole, yielded a dark greenish brown solution, which showed band I. dark, but of no great breadth; band II. faint, with complete absorption towards end of green.

It will be noticed that in none of the extracts were all the five bands present, and further, that there was a certain order in which the various bands were acted upon, whether by dilution or exposure of the solution, or by some change in the extract itself. Bands III., V., IV. and II. were every susceptible, and quickly disappeared in their order, whilst band I., though very persistent, narrowed and became less dense. It is almost impossible to show without unnecessarily lengthening the paper the close relationship existing between the spectra of the different extracts and their age and quality. The age and therapeutic activity of some of the extracts examined happened to be known, so that this is spoken to with some confidence; but even were this not the case the following summation is very suggestive:—Extracts belladonna, hyoscyamus, and cannabis Indica in every case gave from four bands down to one in their order, but were never without band I. at least; extracts aconite and conium in the majority of cases only gave band I., whilst in some cases they gave none; and extracts lettuce and hop, with a single exception or two, never yielded any band whatever.

COMPARATIVE EXAMINATION OF THE MORE IMPORTANT COMMERCIAL VARIETIES OF GALBANUM AND AMMONIACUM GUMS.*

I. GALBANUM.

BY EDWARD HIRSCHSOHN.

(*Continued from page* 533.)

12. *Treatment with Alcohol.*—The residue from the treatment with ether was then treated with 85 per cent. alcohol as long as any went into solution. The alcohol was distilled off and the extract dried at 110° C. and weighed. The quantities of alcoholic residue obtained are shown in the comparative table on p. 531.

The residues were of a dark yellow colour, and dissolved to the extent of about one half. These aqueous solutions were of a full yellow colour, reddened litmus paper, and behaved towards reagents as follows:—

Ferric chloride produced in Nos. 1 to 14, 15 and 24 a darker colour; in the others either a green colour or a green precipitate. Subnitrate of mercury produced turbidity or a slight precipitate. Acetate of lead produced a slight turbidity; subacetate of lead a strong precipitate; gelatine solution no change. Ammoniacal silver solution was reduced in the cold; Fehling's copper solution, only after long standing, but when boiled a strong reduction took place. In contact with washed yeast fermentation took place and a quantity of carbonic acid was evolved.

A larger quantity of alcoholic extract from No. 2 was treated with subacetate of lead as long as a precipitate was formed, and filtered. The filtrate after sulphuretted hydrogen had been passed into it, and the sulphide of lead separated, was colourless, and gave no reaction with perchloride of iron; but it reduced Fehling's solution and gave off carbonic acid with yeast.

This would indicate the presence of sugar, and a body analogous to gallic acid.

13. *Treatment with Water.*—The residue left by the alcohol was treated with water at the ordinary temperature as long as anything was taken up. The extract obtained tasted somewhat bitter, was of a more or less full yellow colour, and had a faintly acid reaction. Evaporated and dried at 110° C., it gave the results shown in the table on p. 531.

The extract from Nos. 1, 2, 5 to 10, 12 to 16, 18 and 20 to 23, were light yellow; those from Nos. 3, 4, 11, 17, 19 and 24 were dark yellow to dark brown; they no longer gave a clear solution in water. Incinerated with soda-lime, they all gave off more or less ammonia. Dissolved in sufficient water to form a thin syrup and twice its volume of 80 per cent. alcohol added, a viscous mucus separated, which when dried gave a more or less yellow vitreous mass, that left, upon combustion, 5·82 to 6·33 per cent. of ash.

The precipitate obtained from all the sorts corresponded perfectly in their behaviour with reagents. All the experiments were made with solutions of equal strengths (1 in 10) and were compared with solutions of gum arabic of the same strength.

Reagent.	Mucus from Galbanum.	Gum Arabic.
Neut. Acet. Lead	Slight turbidity after long standing	No change
Hydrochloric Acid and Alcohol	Precipitate	Precipitate
Perchloride of Iron	Gelatinous mass	No change
Silicate of Soda	In equal volumes a clear solution, but becoming thick	Turbid, becoming thick
Oxalate of Ammonia	Turbidity	Turbidity
Caustic Potash and Fehling's Solution	No action in the cold, strong reduction by heating	Gelatinous mixture; no reduction by boiling
White of Egg, clarified by an acid	White precipitate, not dissolved in excess	Plentiful precipitate, perfectly soluble in exces

A solution containing 10 per cent. of mucus examined in a tube 50 mm. long was without action upon polarized light, whilst an equally strong solution of gum arabic rotated it 1°12′ to the right. Upon boiling a 10 per cent. solution of galbanum mucus and gum arabic for some time with sulphuric acid, and examining the resulting sugars, that from the mucus was almost inactive, whilst that from the gum rotated the polarized ray 10° to the right.

It was not improbable that the precipitate produced by alcohol in the aqueous extract represented a mixture of gum with dextrin. In order to remove the dextrin-like body from the mucus it was again dissolved in water, and precipitated with dilute alcohol until it gave only a very slight reaction with Fehling's solution in the cold. But the mucus thus purified behaved exactly the same as before. An attempt to obtain, by Scheibler's method, a crystalline body similar to arabin sugar from the mucus was unsuccessful, only an amorphous mass resulting. It is, however, very interesting that the mucus from galbanum is optically inactive, and yields an inactive sugar as a decomposition product.

14. *Insoluble Residue.*—The residues not taken up by water were dried at 110° C. and weighed; the results are shown in the table on p. 531. In most cases the residue consisted of fragments of root, stalk, etc., and in the Persian sorts of fruit in various stages of development. The Levant galbanums contained varying quantities of a substance analogous to bassorin, which could not be found in Nos. 1 to 4, 15, 17, and 24 (Persian sorts). Starch was found only in the sorts containing large slices of roots.

* From a memoir for which the gold "Suworow" medal has been awarded by the Medical Faculty of the University of Dorpat. (*Pharmaceutische Zeitschrift für Russland*, April 15, 1875, p. 225.)

15. *Résumé.*—A consideration of the results obtained shows that according to their physical characteristics galbanums may be divided into three classes, one Persian and two Levant. In the fresh condition the Persian kinds are of a very soft consistence; they always contain fragments of stalk and fruit, and have an odour recalling turpentine and galbanum (Nos. 1 to 4, 15, 17 and 24). The Levant sorts have a pure galbanum odour, are either brittle or soft, and may be divided into those which contain stalk fragments and fruit and those which contain only slices of root. The first of these (those which contain fruit and stalk fragments and possess a brittle property) are not now met with in commerce.

According to their behaviour towards reagents the galbanums can be divided into four sorts,—one Persian and three Levant. The Persian and Levant kinds can be easily distinguished from each other, either in the crude condition or as a petroleum extract, by means of sulphuric or hydrochloric acid, the solution of gum resin in sulphuric acid with three or four volumes of alcohol added being with the Persian sorts (Nos. 1 to 4, 15, 17 and 24) a clear yellow brown solution; with the Levant sorts either a red violet colour (Nos. 8 to 10, 13 to 16, 18, 20, 21) or (Nos. 5, 6, 7, 11, 12, 19) a blue violet. Hydrochloric acid gives with the gum resin or the petroleum extract in the Persian sorts a reddish yellow and in the Levant a blue violet or red violet, or no colour at all (No. 23).

A mixture of chloral and chloral hydrate gives with the petroleum extracts of the Persian sorts (Nos. 1 to 4, 15, 17 and 24) an intensely green solution; with the petroleum extracts of the older Levant sorts (containing stalks, Nos. 5 to 7 and 19) a rosecoloured solution, passing through blue into green; with those of the Levant at present in commerce (containing slices of root, Nos. 8 to 18, 20 and 21) at first a yellowish red solution gradually passing into a dirty green, faintly rosecoloured at the edges; lastly with No. 23 no colour.

Frohde's reagent added to the petroleum extracts coloured the Persian sorts, Nos. 1 to 4, 15 and 17, as well as the Levant sorts, Nos. 8 to 18, and 20 to 24, yellow, while the older Levant sorts, Nos. 5, 6, 7 and 19 were coloured red.

Petroleum spirit removed from good sorts of galbanum hardly any thing but volatile oil, the small residues left upon heating to 120° C. were probably the result of oxidation as they no longer dissolve in petroleum spirit. This behaviour of petroleum with galbanum might very well be used in estimating the quality and genuineness of the drugs.

The volatile oil is dextrogyre or levogyre, according to the sort from which it is obtained; its specific gravity also varies. The oil freshly distilled gives none of the characteristic reactions of galbanum; but does so after long exposure to the air. From this it would appear that the body giving the reaction is formed through the oxidation of the volatile oil.

The resin (*i. e.*, the part soluble in ether) appears to consist of at least four different bodies, and yields umbelliferon either by dry distillation or treatment with sulphuric acid and alcohol. This would appear to exist to some extent ready formed, as a portion can be extracted from the resin with boiling water.

It is also worth mentioning that the Persian sorts yield by dry distillation a large quantity of umbelliferon and a very small quantity of blue oil, whilst in the Levant sorts, these proportions are exactly reversed. The melting point of galbanum resin varies between 40 and 45° C., which property may be used to distinguish it from olibanum and similar resins, olibanum melting at 75° C. After galbanum has been exhausted with petroleum spirit and ether, 95 per cent. alcohol removes at the most 4 per cent. more. The residue consists of a resinous body insoluble in ether, and a portion soluble in water. The latter contains fermentescible sugar and a body resembling gallic acid.

Lastly after treatment of galbanum with petroleum spirit, ether and alcohol, it yields to water an inactive mucus from which may be obtained an inactive sugar and a body resembling dextrin.

DOMESTIC PHARMACY IN THE SEVENTEENTH CENTURY.

BY F. BADEN BENGER.

An old manuscript receipt book, dated 1670, lately come into my possession, has interested me by exhibiting the pharmaceutical turn of an ancestor in the time of Charles II. A few of the formulæ may possibly amuse the readers of this Journal, and are perhaps sufficiently curious to be worth preserving.

"*An aproved good watter for the jandies, or the collick, or consumption.*—Take a peck of garden snails and wash them in a great pan of beare, then make your chimney very cleane and power out half a peck of charcole and set them on fire, and when they are throughly kindled then with a fire shovele make a greate hole and power in the snailes and scater some of the fire amongst them, and then lett them roste as long as you hear them make a noyse; then take them out, and with a knife and corse cloth picke them and wipe all the greene froth of them very cleane; then put them in a stone morter and bruis them, shells and all. Take, alsoe, a quart of earth worms, slit them with salt, then wash and beate them in a stone morter, and the pot being made very cleane upon wich you sett your limbeck, put them into it and about 2 handfulls of angellicoe layed in the pot, and 2 handfulls of sullendine upon that, then put in 2 quarts of rosmary flowers; also, if you please, you may put in egremony, barsfoote, dock roots, the barke of a barberry tree, wood sorrell, bittany, rew, and fennell, half a handfull; of fengreeke and turmereck of each an ounce; of saffron well dried and beaten to powder the weaight of a sixpence; then power in 3 gallons of the strongest ale you can gett, greate mesure, cover your pott, let it stand soe all night in the place where you meane to put your fire in the morning, then put to them 3 ounces of cloues in powder before you put fire to it, put thereto six ounces of hartshorne grated to powder—before you put it in weigh it—you must not stir it after you have put in the heartshorn, lett it goe to the bottom, then set on the limbeck and set it fast with rye paste, soe receve the water in a pinte glase; the first is the best, and must be cept by itselfe; the last is the worst, the smalest, and may be mended by mingling them together. This water must be given in the morning to the patient, who must fast 2 hours after it; it may be given betwixt meals. You must take spoonfulls of the strongest with 4 spoonfulls of ale or white wine, and when you give the smalest you may give as much of that as of ale. You may draw six quart of watter from this proportion of things."

"*A pupye watter.*—Take a white pupye of 3 weeks a month old, skin her and take out all her inwards, then wipe it very well within with a cleane cloth, then quarter her in 4 and take a quarter of her with a handfull of femitary, as much wilde tansy, a quarter of a pinte of ants eggs, halfe a pound of fresh beefe thinly sliced; then strow good store of beane blossoms in the bottom of your still, then the forenamed things, then some more beane flowers on the top, then a quarter of an ounce of camphor, soe still it lesurely. The rest of your whelp, with new ingredience, will make 3 stillfulls more."

"*For any acke or pain, or siaticke.*—Take a red ox-gall and half a pint of double brandy, put them into a new pipkin and stop it close; let it simer on some embers 6 hours till it comes to an oyle, and till half be wasted; anoint the place grieved before a good fire, and hold a red hot fire showel to the part most pained. Rub the oyl in very well, then wrap it up in new flannell; soe doe night and morning till the pain is dispersed."

"*To make aqua mirabilis water.*—Take gallingall, quibilis, mellilot, cloves, nutmegs, mace, ginger—of each one drachm and a halfe—beate them to powder; then take 8 ounces of yᵉ iuce of sullendine, one pint of aqua vite, one pott of good white wine, and put them all together, and let them stand close stoped in a earthen pott or glass all night. Then draw through the limbeck aboute a pinte, for the furst tapp is the best, the second stand untell it drop whiter, and the last soe long as it will runne.

"*The vertues of this water.*—Of all water this is the best, for as the name is soe the nature is, miraculous. For it clenseth the lounges without any greuance, and being wounded it healeth them; it sufereth not the blood to putrify, but multiplyeth it in great quantity; it depresseth melancholy miraculously; it ingendreth a good choler; it helpeth the memory and destroyeth the palsy. It must be used continually—one spoonfull a week in sumer and two in winter."

"*A most excellent balsom.*—Take wormwood 3 handfulls, mugworth, rue, rosemary, sage of vertue, leaves and flowers, of each 2 handfulls, boyle them with a sufficient quantity of oyle of nutts, and when the hearbes are boyle enough they will be black. Then take out all the hearbes, leaving the oyle, put them into a strong cloth, and press them very hard, and put this oyle to the other oyle; then put to it a pound of rosen finely beaten, new wax half a pound, Venice turpintine 2 drames, oyle of lavender 2 ounces, sturing it all the time; and when it is all well melted straine it, then put it into a pot well varnished, and stop it well and put it to deggest in a dunghill for six weekes. If you would have it liqued put in but half a pound of rosen. This balsom cures in 24 hours all sortes of green wounds, the wound being furst wash't with white wine. It cures all paines in the head, being apply'd to the temples. It cures deafness, black wool being dip't in it and put hot into the ear. It cures the pain of the stomack, and stopps a vomitting by rubing the stomack with it. It is excellent for yᵉ sciatica. It cures all sorts of collick apply'd upon the stomack or belly. It cures the palsie and all cold pains well bathed in, covered well to make the party sweat. It cures srunken sinues well bath'd in. It cures yᵉ biting of a mad dog, serpents, or other venmous beaste, having first made the wound bleed, then wash it with white wine and lint, then apply the balsom—when you use the balsom put a hot cloth on it."

"*The best watter for the face, may be given to the queen for the pretiousnes of it.*—Take whits of 8 new laide eggs and beate them till they come to a perfect watter, then straine them and take almonds, endiff, boras, camphor, zuchanimum, which is made with alum that is relented, of each of these a quarter of an ounce, and soe mingle all these with as much white rose water as the whits of eggs, and make it up like a suger lofe. Then take of whit wine vinegar 8 ounces, watter of beane blossoms 2 ounces. Let all these things be beaten in a morter very fine, and put them all together into a glase, the which being well covered you shall set in the sun 15 dayes, shaking the saide watter three times a day. This being done put it into another viol glase, and soe keep it for your use, and wash your face when you will, and let the watter dry in, then rub your face with a piece of scarlett. The ladyes that will use it and wash theire face and brest with it, it will make her looke very beautifull and fair, and where she is old it will make her looke yong, for it is well experienced upon a great person whom doth much commend it, which by triall you shall finde far better than I have set downe. The Duchess of Mellin, the French king's sister, use'd it till her dying day, who was four score years old before she dyed, and those that did use to the court said that all straingers hearing she was soe old would not beleeve it, but thought her not to be above 30 or 40, it did so apeare."

"*For heate in the face.*—Take a pint of creame, a quart of strawberries, put in the bottom of your still some vine leaves and still them together, soe wash your face with the watter."

"*For an ague.*—Take chickweed, grounsell and wormwood of each a handfull, do not wash them but shred them small, put them in a fine bagg and with a string hang the bagg to the pit of your stomach an hour before the fit comes on and so repeat it the next; if they be thirsty give them cardus posset is best."

"*An oynment for a burn.*—Take 3 peneworth of letherge of gold, put to it a pint of white wine vineger, set it on a soft fire till it be warm, then let it stand 24 hours, then take one spoonfull of that vinegar and one spoonfull of sallett oyle, put it in a peuter dish, stir it till it come to a white oyntment, then take another spoonfull of each and soe till all be done; put it up in gallie pots and keep it for your use."

"*Cock ale*" is directed to be made from "an old red cock boyl'd indifferent well and pounded flesh and bones in a stone morter," to this is added various spices, "raisins of the sun," and "8 gallons of strong ale." For "yᵉ stone," parsley seeds and "lillie roots" are strongly recommended, as is also "the inward skin of the gisard of a hen or capon dryed and beaten to powder." For "chop'd nippels" "the inner bark of the elm." In "a drinke for sore throate" "album grecum" figures as the active ingredient.

The formula for "*plague water*" enumerates 60 ingredients. The menstruum being three gallons of brandy its potency cannot be questioned. "To draw out a thorn never so deep in 24 hours, lay a piece of the gall of a hog to the place." "What Mr. Tomlinson took" consisted for the most part of garden snails and milk, with "harts tongs, brucklime and maiden heir." "Aqua mellis" is prescribed to "make the hair grow long and curl'd" and emulsion of almonds in sack is much vaunted as a complexion "watter."

I will conclude my extracts with—

"*An excellent receipt to cure any carnal distemper.*—In a sunshiny morning walk in the garden of your heart, then take the pruning hooke or weeding knife of godlie sorrow to cut up the weedes, idlenes, negligence and sloth, then goe to God's garden, take one drachme of time, one drachme of the herbe of grace and an heartfull of bible worth, mix them carefull with one quarter of an houre of the powder of prayer, boile it with the fire of zeale, then put it in the gally pott of conscience and let there be a leather cover of constancy tied fast with a twisted threade of charitie and humility; the time to take it is in your youth, especially on holie days; when you take it get a liquorish stick of meditation, then it will goe downe pleasantly, take the spoone of conference and let them tast it; this medicine, *probatum est*, your doctor is an old greate phisitian called heavenly wisdome, hee dwelleth in Gracious Street, at the sign of humilitie, hee will send you to an apothecary called Godlines, hee dweleth in Love Lane, at the sign of the lamb; hee hath an apprentice called Diligence to make your ingredients."

LIBERIAN COFFEE.*

From the great interest which has attached to Liberian coffee, as much in a commercial as in a scientific point of view, owing to its reputation as to quality and prolific bearing—and, not least, its reputed power of being disease-proof—the replies to a series of questions regarding the cultivation and production of coffee in Liberia will be of especial interest to many readers of the *Journal*. The plant producing Liberian coffee is distinguished from the ordinary coffee (*Coffea arabica*) by its more robust habit, its larger leaves, and much larger berries and seeds. It is now considered to be a distinct species, and has been described as *Coffea liberica*. The questions referred to above were drawn up by Dr. Thwaites, the Director of the Royal Botanic Gardens, Peradeniya, Ceylon, and the replies have been obtained by Messrs. Irvine and Co., of Liverpool. From these replies it seems that the Liberian coffee grows equally well in the immediate neighbourhood of the sea and at considerable distances from it. Under like conditions of soil and cultivation, trees near the seashore in Mourovia are about the same as those at Careysburg and other places thirty miles distant. The wild coffee, from which the cultivated comes, is found at even still greater distances in the interior. At Bassa and Sinon the coffee-trees are said to grow within a hundred yards of the sea. The general temperature at which coffee thrives best ranges from 72° to 87° Fahr. in the shade. In the country, at the furthest point at which coffee is cultivated by the settlers, there is a difference of one or two degrees lower, owing principally to the rise in the land. The lowest temperature observed at Mourovia near the sea was 62°, at seven o'clock, a.m., in the month of January, during the prevalence of the Harmattan winds, the highest temperature being 91°; but these are exceptional cases. Along the coast the coffee-tree thrives at only a few feet (about ten) above sea-level. At Careysburg, and at Mount Coffee, it succeeds as well at an elevation of 550 feet. It grows equally well on level ground as on slopes. In the former situation, however, care should be taken not to allow water to stand; and in the latter the rich mould, or surface-soil, should not be washed away. "While the leaves of the coffee-tree delight in frequent refreshing showers, the roots are averse to standing water." With regard to soil, that of virgin forest is recommended as best for coffee culture, simply because it contains sufficient plant-food, and saves the expense of manuring for several years; ordinary soil, however, will answer, provided it contains sufficient plant-food, or otherwise can get a sufficiency of manure. A loose soil is most suitable. The tree will not thrive in stiff clay. Distinct varieties of the plant are known, one of which produces fruit at an earlier age than the other; the berry, also, is smaller. The large variety, however, is preferred, as yielding a superior quality of coffee and a larger crop. This larger variety, again, varies in itself under changed conditions of soil. In the moist lowlands the berry is very large, while in the dry rocky hills, or uplands, it becomes somewhat smaller, but of a finer flavour. The trees on a single plantation produce berries varying in size to some extent. It does not appear to what extent high cultivation would produce a crop of more equable size. It has been proved that planting a nursery with seeds of a uniform size does not produce uniform plants.

Under shade both the quality and quantity of the coffee crop is much diminished. "When the trees are not large enough to shade the ground with their branches and fallen leaves, they should be mulched in the dry season; that is, their roots should be covered with dried grass, straw, shavings, or anything capable of shading them. But the leaves and branches should have the influence of the sun, to elaborate a due proportion of sap into fruit-buds." The species being indigenous to Liberia, it does not, of course, when once established, suffer from the tropical suns of the country. Mulching in the dry season is generally required, for very young trees on dry, hilly slopes.

The distance at which trees are planted from each other varies; sometimes they are placed at a distance of 6 to 8 feet, and others 10 to 12 feet. If planted sufficiently close that their branches meet, provided that these leaves and branches have the influence of the sun, they thrive and bear well. The shade they cast upon the ground also prevents the growth of grass and weeds, and so the expense of weeding is saved. When planted so close, however, some inconvenience is felt in passing among the trees for manuring, pruning, or gathering the crop. When planted even at the distance of 12 feet, if the trees are topped and kept down, they will eventually meet. The small variety before referred to begins to bear at eighteen months, the larger form in the third year; this variety has, however, been known to bear sooner. The first crop is usually only a few berries, but the tree goes on increasing until it becomes capable of yielding twenty pounds, and some very old trees have been known to give twenty-four pounds each, but more generally depends upon cultivation than upon age. The tree, if left alone, grows to a height of 20 feet or more. In some plantations they are allowed to grow up without being touched, while in others they are topped, perhaps at a height of five feet. By topping the crops are more conveniently gathered, and, others things being equal, give a larger crop. When the trees grow up tall, moreover, they are frequently injured by climbing with ladders, and pulling down the limbs, etc., and as the tree ripens its crop and blossoms for the next year at the same time, much of the blossom and young fruit is rubbed off the tree, whereas the low trees are picked by standing on the ground.

Owing chiefly to the fact the most of the Liberian plantations are young, manuring is not practised to any extent, but when needed the coffee pulp is used mixed with cattle manure, also decomposed vegetable matter, wood ashes, the "compost heap," the earth from the hills made by white ants, etc. The coffee-tree delights in nitrogenous manures; surface manuring is considered best on account of the fibrous roots, or feeders, always keeping near the surface.

Though there are no very old plantations in Liberia, it is believed that they can be kept up permanently, or at least, for a great number of years. It is pointed out that the coffee plant is not a shrub but a forest tree. There are trees in the country forty years old, flourishing in all the vigour and verdure of youth, and bending down under the weight of berries. Some of these old trees, when cut down, shoot up more rapidly and more vigorously than when first planted from seed.

A most important point is touched upon in the matter of the liability of the Liberian coffee to disease. On this subject the writer says:—"Last year some of the trees on different plantations were affected with what was said to be the disease *Hemileia vastatrix*. The leaves of the trees turned yellow (although want of cultivation will cause the same phenomenon); there was a tendency in some of the upper branches to decay and dry up the berries before they could ripen. This may have happened before; but it was observed only last year. Occasionally the bark of a tree will decay, partially or wholly; when wholly it causes the death of the tree. Occasionally, a borer will attack a tree. Nothing as yet has been observed that would cause serious losses of coffee growing in Liberia." The author of the replies thinks "that the yellow appearance in some trees was owing to the want of cultivation. Some of the trees supposed to be diseased were as full of berries as the other trees."

It is further pointed out, in the circular from which the foregoing are abstracts, that it is very desirable that small branches of the trees on which are leaves affected with the disease should be rapidly and carefully dried for transmission to Kew, and to Peradeniya, for comparison with specimens of Ceylon coffee affected with *Hemileia vastatrix*.

The Pharmaceutical Journal

SATURDAY, JANUARY 13, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

TRADE INTERESTS AND THEIR DEFENCE.

IN the present number of the Journal we place before our readers a report—somewhat after date it is true—of the case tried before the Runcorn magistrates, on the 27th of December last. Without raising any question as to the good intentions and zeal of the Chemists and Druggists' Trade Association, which we believe to be all that could be desired, we cannot refrain from expressing a hope that in future the proceedings undertaken by this body for the protection of the trade will be more adequately adapted to secure the object for which they are designed than we are able to admit they have been in this instance.

Much unnecessary trouble seems to have been taken in the cross examination of the inspector of weights and measures, who purchased the sample of milk of sulphur, and of the analyst who certified that it contained hydrated sulphate of lime to the extent of 58 per cent. In neither case was any other result produced than that of wasting time, wearying the magistrate, and confusing the real question at issue by miserable sensational assertions about plaster of paris and its elements, of which any one pretending to a competent knowledge of chemistry ought to be ashamed, and of which any one possessing an average acquaintance with the application of chemistry to pharmacy would not venture to be the exponent.

We regret that the directing authorities of the Chemists and Druggists' Trade Association, in their laudable endeavour to exercise, in behalf of trade interest, the protective function which is supposed to be in abeyance, should not have manifested a better appreciation of the merits of the question they undertook to contest, and a more judicious sense of the means by which it was to be decided, than to enter upon a kind of discussion with the public analyst which in itself gave some apparent weight to the opinions he thus gained an opportunity of expressing. Whether or not MR. CARTER BELL considers that milk of sulphur ought to be pure sulphur is a matter of little moment in itself, but when he, as a public official, comes to be cross-examined on the point in such a case as that tried at Runcorn, the view which he expresses acquires practical value altogether disproportionate to its possible intrinsic value. The value of MR. BELL'S opinion in its application to the custom of the public and of the trade by which the wants of the public are supplied, we consider to be *nil* in this particular case, and further that he was altogether exceeding his functions as public analyst when he ventured to assert that "milk of sulphur" ought to be all sulphur, and not to contain any hydrated calcium sulphate. In doing this he places himself in direct antagonism to the best pharmaceutical opinion of the day, and to the popular opinion which has prevailed for more than a century, on the basis recognized, if not furnished originally, by no less an authority than the College of Physicians. Upon what pretext MR. CARTER BELL, who admits that he knows nothing whatever of the trade, presumes to override these justifications of the use of milk of sulphur, we are at a loss to conceive, and we can only express our admiration, in one sense of the word, of the uncompromising self-satisfaction with which he has delivered himself of opinions which were as destitute of any tangible foundation as most of his hearers were of the capability of appreciating their value.

We have here another flagrant instance of the misuse of a public office which might be a means of rendering good service to the public, but as used for the most part hitherto has been more a means of persecution of one section of the public than a source of general benefit. We were hopeful when the office of public analyst was instituted that this step would conduce not only to the advancement and recognition of chemistry as a practically useful branch of knowledge, but also to the benefit of the public at large and are still of opinion that these might have been the results of the establishment of public analysts throughout the country. As it is, however, the energies of these officials seem to be in many instances exercised in such a manner as to make them to be regarded as public nuisances, rather than as useful public servants, and in the proceeding of certain public analysts with regard to milk of sulphur there is especial reason for this conclusion.

It is, however, satisfactory to know that the Trade Association intends to carry this case to appeal, and we trust that in doing so there may be a more clear recognition of the extremely simple question at issue, for if that course be followed and delusive sentimentalism be excluded, there can be, in our judgment, no question that it will be decided that the sale of a well-known article under a well-known name that has been authoritatively sanctioned for a century and a half is not any more a breach of public morality now than it was when this particular article was comprised in the materia medica of the Pharmacopœia. In regard to this point we have great pleasure in placing before our readers the comments of the *Lancet*, which are to the following effect:—

"When shall we have the last of the wrangles about milk of sulphur? Everyone knows that the article commonly sold as milk of sulphur always contains, and must, from the way in which it is prepared, contain sulphate of lime. It appears to be commonly preferred to the pure precipitated sulphur, and we confess we do not see any reason why it should not be sold if not misrepresented. Milk of sulphur does not mean pure sulphur, but a particular preparation, and we think the Runcorn magistrates were in error in deciding that a purchaser who went to a certain shop for milk of sulphur did not get what he asked for. If he wanted pure sulphur he asked for the wrong article, which was not the fault of the tradesman. The man who wants bread and asks for cake cannot reasonably abuse his baker. Notice of appeal has been given in the Runcorn case, and we trust that a final decision in this not very important question will ere long be obtained."

HOSPITAL OUT-PATIENT REFORM.

WE have pleasure in notifying that the authorities of King's College Hospital have inaugurated a system which acquires increased importance from the numerous cases of poisoning by misadventure which we have to record in the pages of this Journal. In the out-patient department of this hospital all liquid medicines intended for external use are now supplied *in blue glass poison bottles only*. Patients not having these bottles are required to pay for them, cost price being charged for all the sizes which are most frequently in use. The system has now had a fair trial, and has been found to work successfully. It is thought that by "educating" the hospital patient to the use of a special bottle for all remedies not intended to be taken internally, a means of safety will be promoted which will be far from ending in negative results. The plan, we are informed, originated with the King's College Hospital Dispensary Committee, which is composed of practical men of high standing in pharmaceutical circles, and we hope the example thus auspiciously commenced will be followed by all similar institutions throughout the country. It may be stated that the bottle to which preference has been given is the "Fluted poison" introduced by Mr. TOOGOOD as specially applicable to external remedies, and now very generally in use amongst pharmaceutists for the purpose.

In the case of the hospital in question, we learn that much attention has been given, and no expense spared, to introduce into the out-patient department all needful reforms. The gratifying results of the system now firmly established, will, we believe, be fully dealt with in the annual report to be issued in March next.

LIVERPOOL CHEMISTS' ASSOCIATION.

ON Thursday next the above Association will hold its Thirteenth Conversazione at the Royal Institution, Colquitt Street, Liverpool. After the reception of members by the President there will be a musical entertainment and an exhibition of various objects of scientific interest. At nine o'clock Mr. W. E. BICKERDIKE is to deliver a lecture, illustrated with experiments, on "The Atmosphere."

THE PARIS PHARMACEUTICAL SOCIETY.

DR. MÉHU, whose name will be familiar to the readers of this Journal, has been elected to the office of Vice-President of the Société de Pharmacie, Paris, for the present year. M. PETIT has also been named Secretary. At the same meeting, the widow of the late M. GOBLEY, acting upon a wish of her deceased husband, presented to the Society a sum of 3000 francs. This event led to a decision of the Society that steps should be taken to have it recognized as an "établissement d'utilité publique," so that it might be competent to receive legacies bequeathed by members or others.

IRISH PHARMACEUTICAL DEFENCE ASSOCIATION.

A SHORT time since the Council of the Irish Pharmaceutical Society, having been asked as to its intention of protecting the rights of those who might pass its examinations, replied that it did not intend to act as a prosecuting body. A meeting has therefore been held in Dublin, at which it was resolved that a Defence Association should be organized for the purpose of preventing any infringement on the rights of Irish pharmaceutical chemists. The subscription is fixed at ten shillings, and Mr. J. T. HOLMES, of Dublin, has been chosen as Secretary.

PATENT MEDICINES IN ALSACE-LORRAINE.

A DECREE has recently been issued regulating the sale of *spécialités* and secret remedies in Alsace-Lorraine. According to it all the preparations that had received the approval of the French Academy of Medicine previous to the annexation of those provinces to the German Empire are still allowed to be sold. But those that had not been so sanctioned, as well as new medicines, must first receive the authorization of a commission sitting at the University of Strassburg, and consisting of M. GUSSEROW, the dean of the faculty, and Professors KUSSMAUL, SCHMIEDEBERG and FLUCKIGER.

THE CHEMISTS' BALL.

WE have great pleasure in calling the attention of our readers to the announcement in the advertisement sheet respecting the Eleventh Annual Chemists' Ball, which is to be held at Willis's Rooms, King Street, St. James's, on Wednesday next, the 17th inst. Tickets may still be obtained from the Honorary Secretary to the Ball, Mr. WALTER HILLS, 338, Oxford Street, or from the members of the Committee, a list of whom will be found in the advertisement. We understand that Mr. JOHN WILLIAMS, President of the Pharmaceutical Society, has been invited to take the chair at the supper.

THE METRIC SYSTEM.

AT a recent meeting of the Medical Society of New York, a resolution was passed unanimously, recommending to its members the adoption of the metric system in writing prescriptions.

Provincial Transactions.

CHEMISTS AND DRUGGISTS' TRADE ASSOCIATION.*

A general meeting of the chemists and druggists of Manchester and district was held in the Memorial Hall, Manchester, on Friday, December 15, at 8·30 p.m.

A deputation from the Chemists and Druggists' Trade Association, consisting of Mr. Thomas Barclay, of Birmingham (the Vice-President), and Mr. Haydon, the Secretary, at the request of the Manchester Chemists and Druggists' Association and School of Pharmacy, attended.

Mr. H. Scott Brown, the President of the Local Association, was unable through indisposition to attend the meeting; he explained that had this not been the case he would have taken the chair.

It was moved by Mr. E. G. Hughes and seconded by Mr. Barclay that the chair be taken by Mr. Slugg.

Mr. Slugg on taking the chair said he had thrown himself into this matter very readily as soon as he thoroughly understood its aims and purposes. He believed the organization to be a sound one and he might say first of all that it was not an organization brought into competition or antagonism with the Pharmaceutical Society. He said that because he believed there had been a feeling on the part of some members of the Council that the Association would work in opposition to them. Now he would assure them there was nothing of the kind, but they came as co-workers and not as opponents. He was, however, very glad when he went to Birmingham to find some members of the Pharmaceutical Council, besides Mr. Richard Reynolds and other eminent pharmacists, who readily supported the Association. They were organizing a society for trade defence, and they might take it for granted that most assuredly they would not defend any dishonest traders, but protect honest men who might be placed inadvertently and through force of circumstances in a position of perplexity and trouble. When such a thing took place it was certainly better to fight the battle by means of a society than individually.

Mr. Haydon explained the origin, aims and objects of the Association.

The Chairman then introduced the Vice-President of the Society, Mr. Barclay, of Birmingham, who said he was glad to meet such a number of his friends, and he thanked Mr. Slugg for his kind introduction. He was obliged to the officers and committee of the local Association for the opportunity they had offered of placing before the chemists of the Manchester district the advantage of the Chemists' Trade Association. In the few remarks he would address to them he would speak of the necessity for such an association as the "trade association," and then he intended replying to some objections which had been made against it, and, in conclusion, offer some suggestions for promoting its success. The necessity for the Pharmacy Act of 1868 was variously viewed by chemists and druggists. There were not a few who thought that it was wrong policy to introduce legislation into the drug trade; they argued that the restrictions imposed upon chemists by the bill for registering the sale of poisons and the responsibility involved by that Act were not at all met by the advantages which were obtained under it. They argued that by the examinations which were necessary to qualify the men to go into the trade they were thereby unfitted for their work. He had heard it said that good assistants could not be obtained now. It was also said that apprentices were becoming more and more scarce. So it was argued that the Pharmacy Act had worked disadvantageously to chemists. He, personally, did not hold with these views; he believed that the Pharmacy Act would eventually be productive of a great amount of good to the chemists of the country. For the fact that assistants were so scarce proved that fewer apprentices were coming into the trade, and notwithstanding the number who passed the examination the Register was year by year becoming less. It was thus evident that by and bye those who were in the trade would reap the benefit. But, however men might disagree about the policy of the Act one and all must agree that they should endeavour to get all the advantages they could under it. Chemists were suffering in many ways from illegal trading, by men who wore not on the Register openly practising as chemists, by grocers and others selling scheduled poisons, and by civil service and co-operative traders. They could really have no conception of the amount of injury from the latter in the South of England. These civil service stores were not only doing a great injury in this country but were doing an injury abroad. He would read to them an extract from a letter he had received from India. The writer believed "that an association for advancing trade interests has long been urgently needed and now more than ever, for the civil service and co-operative stores affected them even in Calcutta. It was not uncommon for those in high pay under Government to send home to the stores for their prescriptions, having them made up in a concentrated form, and he thought their efforts would be supported by every man in the business and by every assistant, for it was in their interest as much as chemists'." As to the question of juries the House of Commons had decided that pharmaceutical chemists should be exempt altogether from serving on juries, and there should be little difficulty in adding chemists, if the matter were taken up by a strong association, such as they hoped to have. The sale of patent medicines was an important question, and they would be glad to have some suggestions as to the best means of dealing with it. They knew that in some parts of the country laudanum, and opium even, were put up as patent medicines. Mr. W. Scott Brown had suggested that the best plan was to do away with the stamp, for if the stamp was unnecessary no one could sell anything containing schedule poisons excepting registered chemists. Speaking of the Adulteration Act he condemned strongly the appointment of gentlemen as analysts who were incompetent to carry out their duties, and who were placed in such a position that the reputation of those who had carried on their business legitimately and never defrauded any one was at their mercy, and they might thus drag honourable men into the mire. He had known instances where men had been placed in such positions, and he thought it was time that some association should take up this question, and he and others thought that as there was not in existence an association of that kind, capable of defending chemists, it was high time such a one was formed. Magistrates were ignorant of technical matters, and, however anxious to do justice, they were misled by blind advisers, and so the blind leading the blind all fell together into the ditch. Mr. Haydon had spoken about the prosecution at Runcorn; he was sorry that their friends at Ashton were not members of the Association, or they would have been defended by it. When the Runcorn cases came before the Law Committee, it was decided to defend them, and the Secretary was immediately instructed to go to Runcorn and obtain the full facts. It had been decided to bring down Professor Redwood, of London, and Mr. Pemberton, a medical practitioner who held a very high position in Birmingham. Mr. Pemberton would tell the Runcorn magistrates that he had for many years prescribed lac sulphuris and he meant it, he preferred it to sulph. præcip. He hoped they would be able to convince the Runcorn magistrates that they ought to acquit their members, and if they failed, they were determined to go to quarter sessions, and contest the legality of the prosecution. Now in Manchester they were happily situated in having professional gentlemen like Mr. Siebold. If all analysts were equal to their friend Mr. Siebold, whom he was glad to see present, they would not find it necessary to complain of the working

* Our apology for publishing this report so late is that it only reached us this week.—ED. PH. J.

of the Adulteration Act. They could also have trained lawyers who could defend them in the police court, and so selfishly they might say, "We need not join your Association—we can defend ourselves." But they would find it both difficult and costly, even in large towns like that, to obtain proper professional help. He would, however, say, that supposing they were able to do this, surely for five shillings a year they would not deprive those in less favoured localities of the protection which would be afforded by joining with Manchester and other large towns. In country districts they had clerical magistrates and analysts who were appointed by them. A chemist prosecuted in those places found it very difficult to obtain the means of defence. It was to be expected when they learned that by a subscription of five shillings a year they would obtain the services of gentlemen like Professor Redwood they would all throw themselves into the Association. Under the Medical Act there might yet be a great amount of trouble. There were not a few medical men, but he thought they were a small minority, who desired to prosecute chemists for prescribing simple remedies over the counter. Such prosecutions would never be sustained if brought before a proper tribunal and fairly defended. The public would demand that the chemist should be allowed to carry on his business as usual. He would next speak of the social advantages. The number of chemists' associations in the country were but few, but eventually the country would be divided into districts, which would be brought together to talk over trade matters, to choose their representatives to the general committee, etc.; local jealousies would thus be overcome and much practical good result. There was a small class of chemists which had a lucrative business with plenty of money at their bankers, who said that they did not wish any society to defend them for they were able to defend themselves; that was a most selfish policy. Though however, these gentlemen would so readily defend themselves in ordinary cases, there might arise some typical case which it would be necessary for the benefit of the whole trade that it should be defended to the utmost and an appeal made to the Queen's Bench; in such a position these gentlemen would probably be disposed to let the case slide—to the injury of the trade, whilst if members of the Association, they would have no hesitation in applying to it to have the case properly defended. He would offer a few remarks in reply to Mr. Frazer, who was a member of the Pharmaceutical Council and the President of the Glasgow Chemists and Druggists' Association. Mr. Frazer had lately given his presidential address at Glasgow, and alluded to the Trade Association. Mr. Fairlie, the Secretary of the Glasgow Association, and a member of the executive of the Trade Association, had challenged Mr. Frazer to prove in debate that he was right in his objections to the formation of a trade association. On Wednesday last there was a meeting, and the subject for discussion was, "Is the Pharmaceutical Society capable of protecting the interests of the entire trade or is the existence of a special Association necessary?" and it was stated that the Secretary would open the discussion, so that, as the President was to be answered by the Secretary, he need not so fully criticize his address as he would otherwise have done. Mr. Frazer was a short time since summoned for selling Liebig's Liquid Extract of Meat, and the result was the exaction of a nominal fine of fifty shillings by the authorities. He was defended by professional gentlemen of Glasgow, and he asked in his address would any Society have done better? His reply was, that if that Society had been then in existence and Mr. Frazer a member he would have been informed that it had been decided in the Bradford Police Court that Liebig's Liquid Extract of Meat was not an article which could be sold with impunity by chemists and druggists except under certain conditions. This information would have been circulated among the members of the Association; the resul would have been a clear saving of forty-five shillings, an amount which would, he thought, be patent to the understanding of any Scotchman. Mr. Frazer said "If we restrict others from selling drugs and patents we must in all fairness begin by ourselves giving up the sale of the thousand and one articles other than drugs now sold by druggists all over the kingdom. This, I suspect, would be giving 'two rich Rolands for one poor Oliver.'" Mr. Frazer here forgot that chemists and druggists were not in the position of ordinary traders and it was not proposed to restrict the entire sale of drugs to chemists and druggists. The object of the Association was to prevent illegal trading in poisons by civil service stores or by other vendors who illegally supply them. It was claimed that chemists and druggists have passed examinations and submitted themselves to the various restrictions of an Act of Parliament, and that these poisons should only be sold by chemists and druggists. Therefore, Mr. Frazer did not put the matter fairly when he said that chemists and druggists must not interfere with these illegal traders if they themselves continued to carry on business as usual. All that was asked was simply that the law should be enforced. Mr. Frazer said that "these troubles of druggists only begun when we got tied neck and heel by the Act of 1868." That was strange language for a gentleman to use who was a member of the Council charged by Government to administer the Act; his place one would think should be outside endeavouring to obtain its repeal. Then he went on to defend the keeping of "open shops" by surgeons. Amongst the letters he (Mr. Barclay) had received at the time the Association was commenced were many from Scotland, one from a small town in the north of Scotland. The writer said he was the only chemist, and there were besides three "open shops" all kept by qualified medical men. The surgeons each kept a boy who attended to the retail counter and dispensed the prescriptions. The result was that the chemist, although a Major and honours man, was prevented from exercising his proper calling, and had to sell all sorts of things to obtain a living, and never saw a prescription, except it might be a "foreigner." He would say this state of things could never be right, for the medical men were not content with the dispensing, but they endeavoured to do all the retailing of medicines as well. Mr. Frazer said further, "Indeed in many villages and towns a surgeon pure or a druggist pure cannot be maintained, and I hold it is for the advantage of the public that the surgeon should keep open shop; the doctor can do the whole work of the druggist, but the druggist cannot do the whole work of the surgeon. But while I say so much on one side, I go as far as anyone here in condemning as unwarranted, the wholesale rush on our business by medical men in towns such as our own, where there is ample scope for the display of their energies in their own proper field, and where there is certainly no lack of efficient druggists; they ought to aim at taking a higher social position than is compatible with their continuing to keep open shop." Mr. Frazer then went on to recommend present "outsiders" to join the Pharmaceutical Society. He admitted, however, that it is said that many of these chemists cannot afford to pay the "guinea" a year to enable them to do so, and said he feared this might be true of too many. He (Mr. Barclay) would reply by saying that another member of the Council, and by no means a warm supporter of the Association, stated that the subscription fee of five shillings to the Association was too high, and that unless it were made half-a-crown the trade would never be got to come in. Mr. Frazer, again, went on to say, "Of course I am aware that the origin of the Society is due to the existence of these very troubles," and he gave credit for singleness of eye to the promoters of the Association. Although he criticized Mr. Frazer's address, yet he gave him equal credit for a desire to do what was best to promote the best interests of the trade, and in making these criticisms he hoped Mr. Frazer would take them in that light. He (Mr. Frazer) also said the remedy was worse than the disease it was intended to alleviate, if not to cure. It appeared, to him to be not overstating the case to say it was equivalent to the swinging of a huge sledge-hammer by a brawny blacksmith to exterminate a fly that had settled on the brow of a fellow-workman. No doubt the fly would be exterminated, but what of the unhappy victim of his affection? Mr. Frazer, with the instinct of an apothecary, introduced the fly—the historic fly—into his address, whether with the usual effect he would ask his hearers to judge. Mr. Frazer spoke of the brawny blacksmith, he (Mr. Barclay) for one thought there had been in the past too much tinkering, and a brawny blacksmith with a sledge-hammer was very useful, especially if the workman were skilful. He challenged Mr. Frazer to deny that the Association was not managed by those who were careful and capable of conducting it properly; he need only mention the names of men like Reynolds, Hampson, Rimmington, Greenish, Savage, their friend Johnson there, and others who were its supporters, to show that it demanded respect and confidence. Many chemists said they ought to get all that this Association proposed to accomplish done by the Pharmaceutical Society. If that were possible he would retire from the trade association to-morrow. The Pharmaceutical Society spent in 1875 a few hundred pounds, and at the end of the year he knew there was a feeling amongst some of the Council that they had spent more than they could afford. He said, how was it possible in such a state of things that they could undertake to put down the co-operative trading in poisons, or protect chemists who were unfairly charged under the Adulteration Act, and other work of the kind? There were only two or three thousand men in the Society, and it was unfair to expect three thousand men to defend the whole of the trade. It would be most unwise to take the Pharmaceutical Society into the law courts of the country, it would place the Society, which was now an educational body and had the charge of administering the Act, in a false position; it would never do to "run the risk of a rebuff and failure" in these matters; it would do the Society great injury. He held that the men who were opposed to the formation of this Association were doing much to damage the position and influence of the Pharmaceutical Society, for they would necessitate its doing the work which only a trade society could properly discharge. In any proposed legislation what help might not the Pharmaceutical Society derive from the co-operation of this Association? for at present it could not speak with confidence, representing as it did a minority of the trade. If the Trade Association represented some 8000 members then it could go to Parliament if necessary as a powerful organization and do some good. What help would an association of that kind have been when the Adulteration Act was before the House of Commons! But it was not then in existence. The pharmaceutical chemist would, he believed, have secured a much better position than he now held and the title of Pharmaceutical Chemist would never have been allowed to be taken as it was under the Irish Pharmacy Act. After referring to Mr. Sandford in eulogistic terms as the author of the Pharmacy Act and alluding with pleasure to his manly avowal of his belief in the usefulness of the Association, although he had been at the outset one of its strongest opponents, Mr. Barclay said that they must have 8000 members and an income of £2000 a year. Mr. Haydon told him there were 8000 chemists and druggists in business in England. He hoped every chemist throughout the country would join the Association and rally to the standard, and they would then have a real and a powerful organization, and when any attempt at legislation was made an organization like theirs would prevent any mischief being done. An organization not powerful to sustain adulteration, not powerful in doing any illegal act, but, powerful in securing the just rights of every chemist in Great Britain.

Mr. T. G. Gibbons then moved "That this meeting having heard the aims and objects of the Chemists and Druggists' Trade Association as described by the Vice-President and Secretary, heartily approves of the same, and pledges itself to support the Association by every means in its power." He said the Secretary and Vice-President had so far exhausted the subject that there was little more for any one to say. There was one matter, however, that of finance, which must not be neglected; they could not get on without money. The only way they could succeed would be for every member to endeavour to bring in others, and as far as his means permitted subscribe to the funds. He had looked at this question from the commencement. He knew if they went to a court of law or to Parliament, it meant money, and if they obtained 8000 members at five shillings each, it would only amount to £2000 per annum, and he did not think that was too much. If everyone did his best he had no doubt the Association would succeed.

Mr. Bostock, of Ashton-under-Lyne, seconded the resolution. He said he was glad to see so many Manchester chemists take an interest in the Association. It was necessary that there should be some united action, and he thought this could not be better attained than by supporting the Association. He had very great pleasure in seconding the resolution.

Mr. Siebold said he was sorry the Ashton chemists did not offer a better defence in the recent milk of sulphur prosecutions in that town; he felt sure had they done so they would have obtained assistance which would have utterly defeated the objects of the prosecution. He would have been willing to have given any amount of time and to have appeared as a witness and declare before the magistrates in a most emphatic manner, as a scientific man, that the prosecution was in the wrong. He should like to see more *esprit-de-corps* amongst members of the trade. He most certainly thought the Association should be taken up by all, and he was prepared to give the cause his utmost support. He thought the recent prosecutions taking place in their vicinity should give a great impetus to the movement.

Mr. Gibson said he went heart and soul into the objects of the Association and he should be very glad to become a member and do all he could to forward its aims. He could not, however, quite agree with all the remarks made by Mr. Barclay; they should remember that they lived in glass houses and if chemists wished to restrict the sale of drugs to members of the trade they should on their side give up selling groceries, etc.; he believed in free trade. Again he thought the remark made by Mr. Frazer at Glasgow, which Mr. Barclay disagreed with, to the effect that in many small villages the doctor could act as both doctor and chemist, whereas the chemist could not act as chemist and doctor, was a very sensible remark and that Mr. Frazer was quite justified in making that remark.

The resolution was then carried unanimously.

The Secretary announced that already about 120 Manchester chemists had joined the Association.

A vote of thanks to Mr. Slugg for presiding terminated the proceedings.

Parliamentary and Law Proceedings.

The Sale of Milk of Sulphur.

At the Runcorn Petty Sessions, on Wednesday, December 27, 1876, Mr. George Marshall, chemist and druggist, was charged for that on the 1st December instant, at Runcorn, he did unlawfully sell to one James Steen, an inspector of weights and measures, a certain article or drug, to wit, two ounces of milk of sulphur, the same not being of the nature, substance and quality of the article demanded by the said James Steen.

Mr. Glaisyer, Solicitor to the Chemists and Druggists' Association, appeared for the defendant.

James Steen deposed to the purchase of two ounces of milk of sulphur, the transmission of the sample to the analyst, Mr. Bell, and the receipt of his certificate. [Certificate handed in, and read: "The said sample is adulterated with 58 per cent. of hydrated sulphate of lime, or the elements of plaster of paris.—Signed J. CARTER BELL. 4th December, 1876."]

What body are you appointed by?—The magistrates of the county.

You say you asked for milk of sulphur?—I did.

Do you know an article called "precipitated sulphur?"—No, I do not.

You made no mention of such substance?—No.

Had you been supplied with the article milk of sulphur on previous occasions?—On this day in question I obtained three samples, and that is the first time I asked for milk of sulphur.

Was this the first of those three occasions?—No, it was not.

Was it the second?—No, it was the third.

In each of the preceding cases did you receive a similar article?—Yes. I asked for milk of sulphur at the three places, and I received it as such, and after I had obtained it I sealed it, and sent it to the analyst.

Did the defendant say anything to you about precipitated sulphur?—I don't remember what he said about precipitated sulphur. Since then I have heard him say a good deal.

Did he say the article supplied was not pure sulphur, but a preparation sold as milk of sulphur?—That was after I got it, if he did say so.

Was it previous to your saying that you were going to have it analysed?—No. I will swear that.

The Clerk: Nothing was said up to that time; in fact, the article was supplied to you without any observation at all?—Yes, sir.

You informed him of your intention to have it analysed, and offered to divide it into three parts?—Yes, sir. I offered to divide it into three parts in all cases. That was my instruction.

What did he reply?—That it was not necessary.

What did you do with the sample when you received it?—I brought it down to the station, sealed it up, and sent it away to the analyst, in a box, nailed up securely.

What day was that?—It was sent away on the same day. I received it back again with the certificate on the 5th of December.

Did the analyst return any part of the sample?—Yes, it's here.

May I just ask whether the sample, when you purchased it, was sealed in the presence of the seller, or at the station?—Not in his presence. It might have been if he had required it.

Joseph Carter Bell, of 12, Radford Street, Manchester, examined by Mr. Day (magistrates' clerk), deposed to the receipt of the sample, which on analysis he found to contain 58 per cent. of hydrated sulphate of lime.

Do you call that milk of sulphur?—Impure milk of sulphur.

In what respect is it impure?—Because milk of sulphur ought to be all sulphur.

What did you do with the sample after you had analysed it?—Sealed it in an envelope and sent it back to Superintendent Steen.

Cross-examined by Mr. Glaisyer: By your certificate you say the sample is adulterated with 58 per cent. of hydrated sulphate of lime, or the elements of plaster of paris. What hydrated sulphate of lime is that which you found present?—Well, it is the ordinary sulphate of lime with a water constituent.

That you call hydrated sulphate of lime?—That is the true term for it.

Is that plaster of paris?—I say it contains the elements of plaster of paris. Plaster of paris is nothing more than sulphate of lime and water, your worships. If you wish to make a plaster of paris image, all you want is a little water to it, and you get the same thing again. Sulphate of lime mixed with this milk of sulphur is nothing more than sulphate of lime watered.

Mr. Glaisyer: That is to say there are not in the sample the usual constitutents of milk of sulphur?—Not! all pure milk of sulphur.

Is milk of sulphur mentioned in the last Pharmacopœia—No.

The Clerk: That is 1867. There is no mention of it in this book. [Produced.]

Do you find sulphur præcipitatum?—It is the same thing.

Were they at any time distinct preparations?—Distinct? No.

Do you know a work—I can't say, a hundred years ago?—In 1746 the Pharmacopœia ordered it to be prepared in a slightly different way by adding sulphuric acid instead of hydrochloric acid.

Do you know a work published by Mr. Gray in 1836 called 'A Supplement to the Pharmacopœia and a Treatise on Pharmacology'?—No. I don't.

Will you read what it says of milk of sulphur?—Your worships, you must understand that this book is for manufacturing and for practical purposes, and of course it is to the interest of the manufacturer to make as much out of his products as he can.

I would rather you read it first.—I want to explain (after looking at the book). This has nothing to do with the case at all. There are several ways of making it. One man may make 3 lbs. of milk of sulphur of 1 lb. of sulphur, and make a poor article, whereas another may make only 1 lb. of milk of sulphur out of 1 lb. of sulphur. Any tradesman may make 3 lbs. of sulphur out of 1 lb.

[Book put in and read.] That is a preparation for milk of sulphur, is it not?—In the course of preparation the lime would be precipitated; sulphate of lime adds to the bulk of the article and increases its weight.

What would be the distinction between these two preparations?—One would be pure sulphur and the other would contain about 60 per cent. of sulphate of lime.

That would be the first preparation under the head of milk of sulphur?—Yes, and it would be a great advantage to the man who makes it.

Would it produce an article similar to what you have examined in this case?—It would.

Would the second produce an article known as precipitated sulphur?—It would, and milk of sulphur too.

Mr. Glaisyer: That I contest.

Is not the same preparation mentioned by the same name "precipitated sulphur" in the last edition of the Pharmacopœia?—I have not looked at it. [Book handed in.]

Precipitated sulphur?—Yes [reading receipt]. That is precipitated sulphur or milk of sulphur.

Is it the same mentioned as the second preparation?—Yes, that's right.

Is the name "milk of sulphur" mentioned in the last Pharmacopœia at all?—It is not.

The Clerk: It is mentioned here in one book forty years old, but not in the one nine years old.

Witness: That is so.

Sulphur præcipitatum is manufactured at the present time according to the formula mentioned by Mr. Gray in 1836, is it?—I don't say so.

You said it was identified with the same preparation. [No answer.]

[Question repeated.] That is the same that is right under the head of sulphur præcipitatum.

Is milk of sulphur now made according to the first preparation named by Mr. Gray?—Milk of sulphur ought to be made rather; but it is not called milk of sulphur but precipitated sulphur.

The Clerk: Now milk of sulphur is synonymous with sulph. præcip?—Yes.

You say the name "milk of sulphur" is not there at all, and yet they were distinct according to Mr. Gray in 1836. Now, is it mentioned as a synonym in the present Pharmacopœia?—No, it is not.

Are both preparations mentioned by Mr. Gray still made?—I should think so.

Are they sold as distinct substances?—Not to my knowledge.

Are they used as distinct substances?—I believe not.

Can you go into a shop and ask for sulphur præcipitatum, or for milk of sulphur?—Well, I daresay you can.

Do not chemists keep both?—As an instance, I may say we have sent for nine samples in Salford; eight of them are perfectly pure and one is adulterated.

So you get both in fact?—We asked for milk of sulphur at the nine shops we visited.

I must press you for a direct answer. Can you go into a shop and ask for precipitated sulphur and milk of sulphur and get either article. You say both are prepared?—I don't know, I have not been asked for it.

How are you engaged, Dr. Bell?—I am the public analyst for the county.

Engaged in business as a chemist?—No.

Nor a dispenser?—No, nothing of the sort. I have nothing to do with buying samples. I simply analyse what is sent to me.

Is it the custom of the trade to provide two distinct substances?—I know nothing whatever about the trade.

Does milk of sulphur mean pure sulphur?—It ought to.

Then it does according to your theory?—I should say decidedly so.

How do you come by that?—Because a hundred years ago there was only one adulterated article prepared with sulphate of lime sold; now, since the Adulteration Act has been put into force, the pure article is sold.

Do you know what the original preparation was in the Pharmacopœia of 1721?—I don't know. I have not read it. One about 150 years ago directs sulphuric acid to be used, and I believe since then, in all the editions of the Pharmacopœia it has been discontinued. In 1746; I don't think there is one after that.

Is not the preparation of milk of sulphur well known to contain sulphate of lime?—Impure milk of sulphur; yes, it is well known.

You say it is quite an alien preparation. Has it ever been officially forbidden?—I can't say.

Are you prepared to say that milk of sulphur prepared so as to contain sulphate of lime is an adulterated article?—Yes.

On what grounds?—Simply because it contains a foreign ingredient which is not pure sulphur.

But is it prepared according to the formula?—It is not.

Which formula?

This formula.—It is not called so, because precipitated sulphur and milk of sulphur are synonymous.

You can't prove that. I have shown they are distinct. You say it is not mentioned as a synonym?—Would you allow me to read from the various works?

I would rather have the works themselves.—They are perfectly correct what I am going to read.

The Clerk: You are fully entitled to go on.

The witness then read extracts from the *Analyst*, page 65, of June 30th, 1876.

Then, as I understand it, you base your grounds on other people's opinions?—Exactly; the same as you do.

Yes, I don't think I need trouble you to read anything further, but I will ask you, does milk of sulphur, prepared in the way Mr. Gray recommends, mix readily with water?—Yes.

That is when it contains sulphate of lime?—Yes.

Does precipitated sulphur mix with water?—No, not quite so readily.

Does the presence of sulphate of lime aid in dissolving the milk of sulphur?—Well, I can't say, because I have not made any experiments upon it. I don't think it does; I don't think so.

Does milk of sulphur, when dissolved in water, produce a liquid of milky appearance?—Milk of sulphur would not dissolve in water.

You have just said it would?—It forms a mixture, but does not dissolve.

Does it cause a milky appearance?—It does.

Is the milky appearance caused by the presence of sulphate of lime?—Oh, dear, no.

Is there considerable difference of opinion amongst medical men whether milk of sulphur, prepared with sulphate of lime, or sulph. præcipitatum, is better for use as a medicine?—All whom I have consulted say pure milk of sulphur ought to be used, and they are surprised when a mixture of sulphate of lime and milk of sulphur is used.

Is not the taste of milk of sulphur less nauseous than that of precipitated sulphur?—I don't remember.

Is not its smell less unpleasant?—I don't think there is any difference.

Is it taken more readily?—I don't see there can be any difference. Milk of sulphur is often made up with confections, such as jam, and is easily mixed up. One containing sulphate of lime might perhaps mix a little more easily, but I have never tried it.

Does the presence of sulphate of lime tend to increase the efficacy of the sulphur?—It tends to decrease it.

In other words, it decreases the laxative properties of the medicine?—Yes, it must do so.

Does not sulphate of lime in this preparation act as an aperient in the same way as cream of tartar would?—I don't think it would. It has rather the opposite effect.

The Clerk: Is not really the question before the Bench whether or not Mr. Steen had supplied to him the article he asked for? and then the question comes whether now, according to the new Pharmacopœia, milk of sulphur is not pure sulphur? and if so, the question is, has he been supplied with a pure article? It does not state "injurious to health" in the summons, it only states that he has not been supplied with the article he applied for. Do you contend that it contains lime or not?

Mr. Glaisyer: I contend that milk of sulphur and sulph. præcipitatum are distinct preparations.

The Clerk: Look at the Pharmacopœia. Why is the name of milk of sulphur left out?—Because they will not acknowledge an adulterated article.

Mr. Glaisyer: That is not so at all. I am informed there are a number of instances——

The Clerk: Are you going to controvert that milk of sulphur is pure sulphur?

Mr. Glaisyer: Most distinctly.

The Clerk: That is the point. The question of it being wholesome or unwholesome does not arise before the Bench.

Mr. Glaisyer: Well, then, I will ask no further questions.

Mr. Glaisyer then addressed the Bench as follows: I appear here on behalf of the defendant, Mr. George Marshall, and at the same time I represent the Chemists and Druggists' Trade Association for Great Britain; and I may here remark that the Association, whilst it will endeavour to assist the authorities in bringing to justice any persons who infringe the law, will also defend its members against being unjustly harassed by what they regard as groundless prosecutions. The defendant is Mr. George Marshall, a gentleman well known to the Bench, and who has for many years been a resident in the town; he holds several public appointments, has been here for fifteen years, and up to the present time there has been no imputation of any fraud being committed by him on the public, nor any charge of unskilfulness in his trade. The present case is similar to those which have occupied a good deal of attention throughout the country, and the Association is desirous of making this a test case, that it may form a precedent for the future, and settle, if possible, the vexed question whether milk of sulphur containing sulphate of lime should be sold as an article of commerce. They have given me instructions to raise no legal objections which might throw the case for the prosecution over on technical grounds, but to rest my case entirely upon the main issue. The prosecution, to uphold their case, must prove to your satisfaction that the article sold by the defendant is a drug that is not of the nature, substance, and quality of the article demanded by the purchaser. This they have attempted to do chiefly by the evidence of Dr. Bell, and I must ask your attention to his evidence for a few minutes. Dr. Bell in his examination has asserted that sulphur præcipitatum and milk of sulphur are synonymous, and that they should be used to indicate a preparation of pure sulphur, so that the demand of the purchaser for milk of sulphur or lac sulphuris should have obtained the same article as if he had asked for sulphur præcipitatum or pure sulphur. He says that the article supplied by the defendant contains a preparation of hydrated sulphate of lime, and that therefore it comes within these words "that it is not a drug of the nature, quality, and substance of the article demanded." Upon this point I shall argue and produce evidence which I consider almost incontestible that sulphur præcipitatum is a drug prepared according to one formula, and milk of sulphur is another drug prepared according to a distinct formula. Dr. Bell admitted in cross-examination that the terms are to some extent distinct in their meaning, but you must recollect he is here to uphold the prosecution based on his own certificate, and he would hardly admit that which would immediately close the case against the defendant, that these two drugs are as distinct as their names imply. If he did the Bench would have scarcely any discretion but to dismiss the case. I shall presently prove, at least, I hope so, to the satisfaction of the Bench, that these two drugs are entirely distinct, and upon that ground I shall ask the Bench to dismiss the summons. If, however, after I have finished my defence, and you have heard the evidence I shall produce, you are of opinion that the defendant has been guilty of a technical infringement of this Act, I must ask you to inflict only a nominal penalty without costs, because I understand that the object of the prosecution in bringing this case before you is not to inflict punishment on the defendant, but merely to try the case. I think I ought, in addition to that, to ask you to state publicly, if you do inflict a nominal penalty on the defendant, that you do not regard his character as in any degree tainted by having sold this article, which is a well known commodity, and was at all events supplied by every person who was asked for it in this town. In order to enable the Bench to decide whether the drugs are or are not distinct, it is necessary I should draw your attention in the first place to the Pharmacopœia of 1721. By this we learn that milk of sulphur may be prepared in either of two ways, one of which would produce a preparation containing sulphate of lime, and the other would produce a preparation which does not contain sulphate of lime. We may fairly surmise that it was found that the former preparation was more favoured amongst medical men, because the latter, which would be made to contain no sulphate of lime, was dropped out entirely from the Pharmacopœia which was next published—that of 1746—and that the other preparation which the public used was that which contained sulphate of lime. Then we come to a later time, and I have put in the book published by Mr. Gray as a supplement to the Pharmacopœia, in which mention is made of the names and modes of preparation of these two drugs, which are certainly quite distinct. I have read the modes of preparation; in the one case Dr. Bell has admitted that the substance produced would be a similar article to that which he has examined; in the other case he has again admitted it would be that which is at present known as precipitated sulphur. He has also admitted that in the last Pharmacopœia the word milk of sulphur does not appear even as a synonym, and therefore no case can be grounded on the fact that precipitated sulphur and milk of sulphur are synonymous or controvertible terms. The greatest argument the prosecution can find is this—that the drug known as milk of sulphur has ceased to be recognized in the Pharmacopœia. Professor Redwood, whom I shall call as a witness for the defence, will give you instances in which other drugs formerly prepared according to the old Pharmacopœia are omitted from the present Pharmacopœia, and upon this I shall argue that milk of sulphur is not tabooed by the profession, but that it is a well-known preparation and constantly used. And further that the preparation known as milk of sulphur should contain sulphate of lime, and the preparation known as precipitated sulphur should not contain sulphate of lime. If the Bench should not be able upon this evidence to decide to dismiss the case against the defendant then I shall have to call your attention to the exceptions which are mentioned by the 6th section of the Act,--and to the first exception I shall confine my remarks—which says "Where any matter or ingredient not injurious to health has been added to the food or drug because the same is required for the production or preparation thereof as an article of commerce, and not fraudulently to increase the bulk or measure or weight of the food or drug so as to conceal the inferior quality thereof," etc. I shall contend that the presence of the sulphate of lime with the sulphur is required in order to make it an article of commerce, and, further, that the sulphate of lime is not injurious to health. On the question of health I consider my evidence ought to be quite conclusive, for I have here two members of the medical profession of the highest distinction and greatest skill. One is Professor Redwood, Doctor of Philosophy and Professor of Chemistry of the Pharmaceutical Society of Great Britain, an office which he has held for thirty years; he is public analyst for three large metropolitan districts, and also for the county of Middlesex; lately President of the Society of Public Analysts, the author of a work on 'Materia Medica' and a 'Supplement to the Pharmacopœia,' and he has been recently appointed by the Medical Council as editor of the 'British Pharmacopœia.' The other is Mr. Pemberton, a medical man of very high standing in the town of Birmingham, where he has a large practice. He is Professor of Surgery in the Queen's College there, and also one of the surgeons to the General Hospital, and he speaks with an experience of thirty years of medical practice. These two gentleman well agree in the opinion that far from being injurious to health, the presence of the sulphate of lime in the milk of sulphur is really an advantage; they will tell you that the sulphate of lime renders the sulphur more active, not only by its stimulating action on the intestines, but by mechanically dividing the particles of sulphur. Mr. Pemberton will tell you the presence of sulphate of lime makes the sulphur more effective, whilst the other preparation causes disagreeable eructations. He will further say that he never but once in the whole course of his professional practice prescribed precipitated sulphur, and that he has always prescribed milk of sulphur, the article sold by the defendant. That milk of sulphur is required as an article of commerce I shall endeavour to prove, and the defendant himself will tell you that for a short time he kept precipitated sulphur; that his customers continually complained of it, and that it was with great difficulty indeed he persuaded them to use it; and that with the exception of a few months he has uniformly kept the article which he has supplied in the present case. No one has ever complained to him of injury received from the administration of the drug which he has supplied in this case. Then, again, I shall call before you Mr. Edward Evans, of the firm of Evans, Son, and Co., of Liverpool, wholesale druggists, and Mr. Matthew Bell, the manager for Messrs. Raimes and Company, wholesale druggists, of Liverpool, who will tell you that they supply milk of sulphur containing sulphate of lime, in quantities far exceeding that in which they supply the other article—precipitated sulphur. Professor Redwood will tell you that it is a necessary article of commerce, and that it possesses a substantial advantage over sulphur præcipitatum, and that it is less disagreeable in taste and smell. Professor Redwood will tell you that it is more readily taken, and mixes more easily with water. That the other (sulph. præcip.) clings about the mouth, that it won't mix with water and the Bench will see that these are not desirable qualities in medicine frequently given to children. Mr. Pemberton will show you that the manufacture of lac sulphuris is absolutely necessary in order that it may be prescribed for patients, and in this way I shall prove all the requirements of the first exception, and upon that I shall ask the Bench to dismiss the summons. I believe, I shall take the case even further than this, and prove that there is no necessity to rely on the exception at all, because I shall prove that milk of sulphur is one thing and sulphur præcipitatum is another thing; and that when the purchaser asked for milk of sulphur he was supplied with a drug which was of the nature, quality, and substance of the article demanded.

The defendant, Mr. George Marshall, was then sworn, and examined by Mr. Glaisyer. He deposed to the sale of the milk of sulphur to Superintendent Steen.

What did he say when you supplied him with the article?—After I had supplied him with it he said, "I want this for the analyst," holding the article out.

And hearing that did you make any reply, and if so what was it?—I told him that it was not precipitated sulphur, it was the milk of sulphur that had been sold for a hundred years. I distinctly told him it was not sulphur præcipitatum.

Did he say anything in reply?—He said he was ordered to ask for milk of sulphur.

Did he offer to divide it in three parts?—Not that I remember.

Was any portion of the sample sold left with you?—No.

Where did you buy the article you sold?—From Messrs. Raimes and Co., of Liverpool.

Have you ever ordered sulphur præcipitatum?—Never but once.

Where did you buy that?—From Evans, Sons and Co.

Do you remember the year?—It was some time in 1872.

Did you supply it to your customers?—Yes, and they returned it more than once, and complained that it was nauseous, and not what I had been accustomed to supply them with. I had great difficulty in disposing of it, but as I had only a small quantity I did not send it back again.

With that exception have you always kept milk of sulphur which contains sulphate of lime?—Yes.

Have you ever received complaints of that article?—Never.

Have you ordered the same article by the same name from other houses?—Always, whenever I have wanted it, as lac sulphuris.

Has there ever been a mistake in sending it?—No.

Have they always sent you the article containing sulphate of lime, with the exception of that once?—Yes.

What is your knowledge of the drug called milk of sulphur?—That it is precipitated with sulphuric acid, and, of course, contains what has been stated. It contains hydrated sulphate of lime, and more readily mixes with water or milk, and these it is often taken with. It is never taken with jams, and that it is more saleable, and is a most useful article.

Is it the article you have always supplied as milk of sulphur?—Yes.

Cross-examined by Mr. Day (the Magistrates' Clerk):

On this packet, which you sold Mr. Steen, did you put a label on "This contains sulphate of lime?"—I put no label at all on.

How much did you charge him for these two ounces?—Twopence.

How much would you have charged for pure sulphur?—I don't keep it, because I have no call for it.

What was your usual charge for the other?—The same price. And very much annoyed I was that I had it, because I did not want it.

Suppose you had been asked for precipitated sulphur, what would you have sold?—I should have sold nothing, because I do not keep it.

You make up doctors' prescriptions?—Yes.

Suppose in a prescription there had been the words, "sulph. præcip.," how would you have made that up?—Decidedly, I must either have sent the prescription back again, or sent to Liverpool, or some other house, to obtain it. I would not think of putting in an adulterated article.

Mr. Matthew Bell sworn, and examined by Mr. Glaisyer.

How are you engaged, Mr. Bell?—As manager for Messrs. Raimes and Co., of Liverpool.

How long have you been connected with the chemist and druggist business?—Thirty-three years.

Is that your trade sheet? [Trade sheet put in.]—It is.

On that trade sheet what do you find under the head of sulphur?—Sulph. sodium, sulph. lotum, sulph. lac, sulph. præcip. pur., and sulph. sublim.

Do you sell those articles as distinct preparations?—We do.

Has that always been done?—Always.

You mention the article on your trade sheet "lac sulphuris." Would that article contain sulphate of lime?—It would.

Is that inevitable from its preparation?—Yes.

You mention sulph. præcipitatum. How is that prepared?—It is prepared by using hydrochloric acid instead of sulphuric acid.

What would the product be from such a preparation?—By the use of hydrochloric acid it would be sulph. præcip. pur.; by the use of sulphuric acid it would be milk of sulphur.

And what would "lac sulphuris," prepared in that way, contain?—Sulphate of lime.

And the preparation with hydrochloric acid, what would that contain?—Pure sulphur.

In your trade do you sell the same quantities of each?—No; we sell much more of the milk of sulphur; very much more.

Can you give us the comparison at all?—I can't say exactly, but from eight to ten times as much milk of sulphur as of sulph. præcip.

The Clerk: Did you supply Mr. Marshall with this article that has been complained of?—Yes.

By the Clerk: Now milk of sulphur is cheaper than sulph. præcip.?—Yes, it is.

What is the price of milk of sulphur?—The wholesale price is 5*d.* per lb. and the other is 8*d.* per lb.

Mr. Edward Evans sworn, and examined by Mr. Glaisyer.

What is your firm?—Evans, Sons and Co., of 56, Henry Street, Liverpool.

How long have you been connected with the business?—Ten years.

What drugs do you sell under the name of sulphur?—The same as the last witness has mentioned.

Do you sell two distinct preparations, one called "lac sulphuris" and the other called "sulph. præcip.?"—Yes, each.

Has that always been so?—Always, ever since I have been in the trade.

What does milk of sulphur, as sold by you, contain?—Sulphate of lime.

How does it get there?—In the process of manufacture.

Is the article known as sulph. præcip. prepared in a different way?—It is.

What does that article contain?—Pure precipitated sulphur.

In what proportion do you sell these two articles?—About four or five times as much of lac sulphuris as pure precipitated sulphur.

Can you give the quantity?—I have looked at our book for 1874, and we sold then about four tons of the milk of sulphur, and six hundredweight of the pure sulphur.

That is about thirteen times as much. What part do you take in the business?—The commercial part more than the chemical part, and I occasionally travel.

Can you tell the Bench of anything that has come under your notice while travelling?—I remember that a woman brought back what she had been served with while I was standing in the shop. She asked for milk of sulphur, and the chemist had given her the pure article. She brought it back, and said it was not the article she required.

The Clerk: How much per pound is pure sulphur?—Witness: Eightpence for pure, and the other preparation fivepence.

Mr. Oliver Pemberton, sworn and examined by Mr. Glaisyer.

Will you tell the Bench how you are engaged?—I am a consulting surgeon, residing at Birmingham. I have been in the practice of my profession for nearly thirty years, and am Professor of Surgery to the college there, and also Surgeon to the General Hospital.

Have you heard anything on this subject lately?—My attention has been called to it simply through perusing the public prints.

And from them what have you learned?—That the question has arisen as to the use of so-called milk of sulphur and so-called precipitated sulphur.

You have heard that the name "milk of sulphur" is omitted from the present Pharmacopœia?—I have.

And that precipitated sulphur is supposed to have taken its place?—I have.

What do you know about the article "milk of sulphur?"—It is a part of my knowledge that milk of sulphur contains sulphate of lime, and also part of my knowledge that precipitated sulphur does not contain sulphate of lime; in other words, is so-called "pure sulphur."

Do you of your knowledge know how the milk of sulphur contains sulphate of lime?—I am aware it does contain sulphate of lime on account of its being prepared with sulphuric acid instead of hydrochloric.

As to the remedial qualities of these two medicines can you give the Bench an opinion?—I would state before coming to that, I regard the two preparations to which I have referred as two distinct drugs, and that I have always so regarded them. The preparation to which I am referring, "milk of sulphur," has been in use especially by surgeons, and is in use for a variety of distinct surgical maladies, in which its special action is supposed to be of peculiar advantage. These diseases are mainly restricted to the lower bowels, stricture of the lower bowel, and disease of the neck of the bladder and enlarged prostate. In these cases it is desirable to obtain a laxative of a reliable character, that would not be likely to produce irritating diarrhœa, which in such diseases would be most injurious, therefore it has been regarded by surgeons, and amongst these by myself, most desirable to make use of this very preparation called "milk of sulphur," because the presence of the sulphate of lime in it moderates its laxative properties.

In your opinion would the same result follow from the use of the other drug?—The use of the other drug would be calculated to produce irritative diarrhœa. I have never myself ordered precipitated sulphur in making up a prescription but once, and that was at the commencement of the present year, when I wanted to write a prescription that was to be dispensed in Paris, and thinking that a popular remedy like lac sulphuris would not be known to the French chemist, I prescribed sulph. præcipitatum, B.P., meaning "British Pharmacopœia." To prove the truth of my general conviction on this subject, I refer to a prescription that is dated November 20th in this present year, which was written before I had the remotest notion of any question arising here or anywhere else on this matter, and it will be evident to those who can read it, there are the words "lac sulphuris," because I knew it was to be dispensed in England and I wished to obtain that which during thirty years I had desired to obtain, and which it was my experience a chemist would use. I felt satisfied he would dispense the lac sulphuris, containing what we have heard of, sulphate of lime. The gentlemen for whom this prescription was written visited me again some week or two since, and I obtained it from him. I have known this preparation of milk of sulphur taken for months and years, and I never knew myself nor heard of any injurious effect following its use. So far, therefore, as my own knowledge of the matter stands, I shall continue to use it. I hope I shall be able still to obtain it as an article sold in the shops, and I should advise those who have to practise the surgical part of my profession to make use of the same article as I have done.

Cross-examined by the Clerk: I understand you to say that the benefit from milk of sulphur is that it reduces its laxative properties?—It moderates or tempers the laxative properties.

Might you not suggest giving a much less quantity for a dose?—By including the particles of sulphate of lime, we don't get a rapid purgative action, and this lac sulphuris softens the motion that has to come away without pain to the patient. In fact, this is a surgical matter. Sulphate of lime tempers the action of the sulphur, and makes the evacuations remaining of the soft consistency of cream, as it were, and so they pass without pain to the patient.

Professor Redwood, sworn, and examined by Mr. Glaisyer.

Will you tell us what offices you hold?—I am Professor of Chemistry and Pharmacy to the Pharmaceutical Society, and have been so for more than thirty years. I occupy some prominent positions, such as public analyst for the county of Middlesex, and three large metropolitan districts. I have been until quite recently President of the Society of Public Analysts, and I have been employed for several ten years by the Medical Council as editor of the 'British Pharmacopœia.' The Pharmacopœia which has been put before you has been prepared by me, under the instructions of the Medical Council. I am author of two or three works on materia medica, and one of the editors of a work that has been referred to, viz., that by Dr. Pereira on materia medica.

Have you given a good deal of thought to the subject now before the Bench?—I have, for many years. I have been practically acquainted with pharmacy for something like fifty years, and during the last thirty-three or thirty-four years I have occupied, as I have said, a prominent position as a teacher in one of the largest pharmaceutical schools in England.

You have heard the evidence of Dr. Bell. Do you agree with him?—No, I do not.

On what grounds do you differ from him as to the terms milk of sulphur and precipitated sulphur?—I consider that the term milk of sulphur has been and still is sometimes used as synonymous with the term precipitated sulphur, but I do not consider that it is so necessarily used, and in the great majority of cases, where the terms are used by the non-medical public, two distinct articles are referred to by those two names. I may further state that milk of sulphur is principally employed by the non-medical public, and by that term they refer to sulphur containing sulphate of lime.

What is the mode of taking it?—The usual mode of taking milk of sulphur—that is the preparation containing sulphate of lime—is by mixing it with water, and the great advantage which milk of sulphur presents, when it contains sulphate of lime, is that it readily mixes with water, whereas that which contains no sulphate of lime will not mix in the same way. This [illustrating the argument by mixing the two drugs] mixes readily with water (lac sulphuris), and forms a milky mixture, in which the whole of the material remains suspended for some length of time, and it can be administered to children and others with facility mixed in this way. Whereas the other, that is precipitated sulphur containing no sulphate of lime, cannot be so mixed. It sticks about the glass and refuses to diffuse itself with water, and if an attempt were made to administer it in this simple manner [as illustrated] it either adheres to the glass or adheres to the mouth and throat of the patient. It is not therefore an available mode of administering it, and it becomes necessary in administering that preparation to resort to the use of something like treacle or syrup. Flowers of sulphur would comport itself exactly in the same way. If we put that into water it will not mix any more than precipitated sulphur will; it floats about and sticks about the glass and does not at all diffuse itself through the water, and consequently in administering either of these to children the method of administration has been to mix it with treacle, and the old brimstone and treacle was the method adopted. These are the peculiar advantages which have led to the public giving preference to the lac sulphuris, the old milk of sulphur, over the more modern precipitated sulphur.

To which is it applied?—The term precipitated sulphur is applied in the last Pharmacopœia to the one that refuses to mix with water.

What processes are comprised under the term milk of sulphur?—In the Pharmacopœia of 1721, under the name lac sulphuris, the process, described in Latin, is to the effect that it is to be made with sulphur and lime, or sulphur and salt of tartar, boiled with water, and then sulphuric acid added.

The Clerk: It is admitted in the old process, but hadn't we better confine ourselves to those of recent date.

Witness: Up to 1788 it contained sulphate of lime. From 1721 to 1746 there were two processes given. There was an alternative mode of making it, so that it either contained sulphate of lime or not. It was then called lac sulphuris, milk of sulphur. Then from 1746 until 1788 there was only one method of making it ordered by the London College of Physicians, and that was the method which yielded sulphur with sulphate of lime. The alternative method had then been omitted. In the paper produced by Dr. Bell (*The Analyst*, June 30, 1876) there are several statements that are erroneous; but if you will turn a page or two over, you will find my statement, which I can vouch for as to its correctness; and I have the books which will substantiate what I say. As a proof that the presence of sulphate of lime received the sanction of the College of Physicians during a period of sixty-seven years, it was ordered in the London Pharmacopœia, and it had during that period passed before a scientific committee. The committee in 1746 was the first scientific committee that had the revision of the Pharmacopœia, and they then omitted the mode previously intended as an alternative method of making it without sulphate of lime, and adopted the method of making it, in which it was produced with sulphate of lime, precisely analogous to the article now before the Court.

You have heard it mentioned once or twice in the course of Dr. Bell's examination that this milk of sulphur is not mentioned in the last edition of the British Pharmacopœia. Can you give any explanation of that?—Milk of sulphur has not been mentioned in any of our Pharmacopœias under that name for more than a hundred years.

Can you give examples of other drugs which are not mentioned in the last Pharmacopœia, but which are still well known?—I can.

The Clerk: That does not bear on the point at all.

Mr. Glaisyer: I understand you were going to make a point of it not being in the last edition of the Pharmacopœia.

The Clerk: Oh no; it does not bear on the question.

Cross-examined by the Clerk: Is the precipitated sulphur you refer to an impure article? Is it so or not?—Precipitated sulphur is not pure sulphur.

Does it contain sulphate of lime?—No. Under the name precipitated sulphur an article which contains sulphate of lime ought not to be sold, certainly.

And you say some parties of eminence, if milk of sulphur is asked for, would expect to receive precipitated sulphur?—There are some, but that I conceive is a mistake.

They consider that when milk of sulphur is asked for they should be supplied with precipitated sulphur, which is the modern representative of milk of sulphur, and does not contain sulphate of lime?—Yes. But I can show you cases where similar changes in the names and composition of medicines have taken place, and where the old preparations, under the old names, have continued to be used.

I don't think the Bench can go into that; we will take it that generally it is so, that is as far as we can expect to go into this matter.

Mr. Glaisyer: Very well, that is so.

The Clerk: Perhaps as that question has been given and you had something to do with the making of the Pharmacopœia, I may ask you is the term lac sulphuris, comprised in the last Pharmacopœia under the term sulphur præcipitatum.?—Certainly not.

Why is it not mentioned?—For the same reason that many other medicines of which I was going to give you instances have been omitted.

If lac sulph. is manufactured, and precipitated sulphur also manufactured and acknowledged in the Pharmacopœia would it not be included in the precipitate sulphur if it was an acknowledged drug?—No certainly not.

Why would it be left out?—The Pharmacopœia does not include all medicines that are used.

If it is a general medicine in consumption is it not rather extraordinary it should be left out?—Not at all. There are other medicines quite as extensively used which are not mentioned in the Pharmacopœia.

You have had instances of it being supplied as thirteen to one, and you say it is not named?—The Pharmacopœia orders those medicines which are intended for use by physicians in their prescriptions. Lac sulphuris is employed by the non-medical public as a domestic remedy.

Suppose a prescription was brought to you, and it said lac sulph., what would you put in?—If it were put in a prescription it would present some difficulty. I should ascertain from the medical man what he intended.

What would it be your duty to put in to make up that prescription? Now, would you not put in sulph. præcip.?—No, I should not. The proper mode of interpreting an expression of that character used by medical men would be to refer to the Pharmacopœia in which that term is used, and if lac sulphuris was the term employed I should refer back to the Pharmacopœia 1721.

But we are in 1876 now, that is rather a long way to go back?—Nevertheless if the name is employed in the prescription it is to be interpreted by the Pharmacopœia.

But, if you looked at your Pharmacopœia, and saw in it the term sulph. præcip., you might supply it, although lac sulph. was used in the prescription?—No, I would not.

You say that milk of sulphur is only used by certain classes as a favourite medicine. Would you not say, if a prescription were ordered containing it, that you might supply sulph. præcip.?—No, I should think not. I would have a strong reason for not putting that, because in the Pharmacopœia, as it stands at present, sulph. præcipitatum is the name employed, and which every medical man in writing his prescriptions ought to be acquainted with and use, and if he used another term—lac sulphuris—I would conclude he did not intend the preparation ordered now, under the name of precipitated sulphur, to be used, but that which was originally named in the Pharmacopœia, as containing sulphate of lime, and which is still used.

Do you not hold that there are many eminent men who might consider that sulph. præcip.?—Not in prescriptions. There are some eminent men and writers on materia medica, who have, as I conceive, not studied the subject to make themselves thoroughly acquainted with it, who hold that the presence of sulphate of lime in lac sulphuris is an adulteration.

These eminent men would use pure sulphur if lac sulphuris is put in a prescription?—No, I don't think they ought to. The preparation containing sulphate of lime possesses advantages over the other, first, that it mixes with water, whereas, the other does not; secondly, that it is more free from taste than the other; and thirdly, that in my opinion it is more efficacious as a remedy; this last, however, is a mere matter of opinion.

Mr. Glaisyer: Are there not other advantages in addition to those?

Professor Redwood then by experimental illustrations showed the Bench the advantages of lac sulphuris over sulph. præcipitatum. The latter breaks up in the stomach, evolving sulphuretted hydrogen, causing offensive eructations, and that is one of the objections urged by the non-medical public when they have been forced to take precipitated sulphur instead of their old familiar lac sulphuris, or milk of sulphur. Precipitated sulphur contains sulphur in an impure state and the other contains it pure.

By the Clerk: But there is lime used in the manufacture of sulph. præcip.?—Yes.

Then would not the term milk of sulphur be included in the term sulph. præcip.?—No.

Chalk would have the same effect to make that milky colour?—Oh, yes, if chalk were put in, but chalk never is put in.

Mr. Glaisyer: In your opinion, is milk of sulphur a proper drug to be kept and sold by chemists?—I prefer it myself, and I consider I have a right to apply for it and use it, and so has the public at large.

By what name?—I know no better name than milk of sulphur by which to describe the preparation containing sulphate of lime, and to distinguish it from the other preparation which contains no sulphate of lime.

The Clerk: Would you not put a label on it, to show what it consists of?—No; I see no reason for doing so. The public well understand it by the name milk of sulphur.

Mr. Glaisyer: It rests on the prosecution to prove that it is injurious to health if it is labelled. That is my case, and I simply request the Bench, on the evidence I have put before them, to dismiss the summons.

The Court then adjourned, and after an absence of three-quarters of an hour the magistrates returned, when the decision was delivered as follows:—

Mr. Bankes said (addressing the defendant): Mr. Marshall, the Bench have very carefully considered the weight of the evidence placed before them this morning, and have decided in this case to convict, on the grounds that you did not supply the article that was asked and demanded. The penalty is £1, and the costs follow as a matter of course.

Mr. Glaisyer: In the other cases I am instructed to consent to the same decision.

Isaac Speakman and Andrew Brown were then fined £1 and costs, for selling milk of sulphur adulterated with sulphate of lime, one 58½ per cent., and the other 65 per cent.

Mr. Glaisyer: I may be allowed to mention that these decisions will be reviewed at the Quarter Sessions.

Conviction for the Use of Methylated Spirit.

At the Newport Borough Police Court on Monday Abraham Clarkson, of Chapel Street, herbalist, was summoned on the information of Mr. James Robinson, supervisor, for having on the 20th of October used methylated spirits and derivatives of methylated spirits in the preparation of an article capable of being used as a beverage, whereby he had rendered himself liable to a penalty of £100.

Mr. Thomas Fell, collector of Excise, Southampton, prosecuted.

Mr. H. R. Hooper, who appeared for the defendant, said he would not put the prosecution to the trouble of producing evidence. No doubt, in total ignorance of the law, the defendant had to some small extent violated the actual letter of it. For a considerable number of years he had been the proprietor of a patent medicine known as "Clarkson's embrocation." Some time since it was found that the preparation was occasionally valued when taken internally, and methylated spirits being used in it, the defendant had thus brought himself within the purview of the statute, but he repeated that he had offended in utter ignorance of the law. Mr. Clarkson was well and favourably known to them as an inhabitant of Newport. He had paid a considerable amount to the revenue, and this was the first time it had been brought to his knowledge that the tinctures could not be used in this way. In future it would be necessary for him to use duty-paid spirits. He need only add that the defendant was an old man of over 70 years, and while the sale of this medicine had kept him above actual want, he had not been able to accumulate any savings, and he trusted such a recommendation would be made to the authorities as would lead to a reduction of the penalty beyond the minimum amount to which the magistrates could mitigate it.

Mr. Fell said the magistrates could mitigate the penalty to one-fourth, and he did not wish to press for a higher fine. There could be no doubt that by the use of methylated spirits there was a considerable loss to the revenue, and the Excise wished to make an example. The Excise authorities could make a still further mitigation, and if the Bench wished it, he would convey a recommensation of that kind.

In reply to a question, a chemist from Somerset House said the greater portion of the tincture would be methylated spirits.

Defendant stated that during the ten years he had been selling this embrocation he calculated that he had not sold more than four gross as drops to be taken internally. He solemnly promised to use nothing in future but duty-paid spirits.

The Mayor said the Bench had no other alternative but to convict, and they fined the defendant in the mitigated penalty of £25. At the same time they were unanimously of opinion that an application should be made to the authorities for a further reduction of the penalty, as they believed the offence had been committed in entire ignorance of the law.

Mr. Fell said he would convey their worships' recommendation to the authorities.

Suicide of an Assistant.

On Monday last at the Marlborough Street Police Court, Mrs. Louisa Murray, the wife of a publisher in Great Tichfield Street, was charged with attempting her life under the following circumstances.—On Saturday night Alexander Lewington, her husband's nephew, about 22 years of age, a chemist's assistant, came to the house where the prisoner lodged and producing a bottle proposed that they should poison themselves. After some time the prisoner consented; she took some of the poison and the nephew, Lewington, took some also. The nephew went away to his lodgings in Cleveland Street and took some more of the contents of the bottle, from the effects of which he died. The prisoner was affected by the poison, but having had medical treatment with sufficient rapidity she so far recovered as shortly afterwards to be able to be brought in custody to this court.—After the evidence of Police-serjeant Jones, E division, Mr. Newton directed the prisoner to be remanded.

The Selling of Poisons.

On Wednesday, January 2, Mr. Alfred Boyce, chemist, of Haywards Heath, was charged at the Cuckfield Police Court with having sold cyanide of potassium to Edward Whitehead, police officer, of Wivelsfield (who committed suicide by its means), and with not having entered Whitehead's name in his books, according to Act of Parliament.

Mr. Boyce pleaded guilty, but explained that he had exercised all the caution he could when serving the poison, and even refused to supply it a week previous, and would not prepare it as the deceased man wished him to. He said that Whitehead represented to him that he was sent by his superintendent, and that he wanted the cyanide to clean his numbers.

The Chairman said that his brother magistrates agreed with him in thinking it was merely an omission, and he would be fined 5*s*. and costs.—*Sussex Advertiser.*

The Attempt to Murder by a Chemists' Assistant.

At the Central Criminal Court, on Wednesday last, before Mr. Justice Hawkins, Thomas William Christison, said to be a chemists' assistant, was indicted for attempting to murder his landlady by administering poison to her, under the circumstances recorded in this Journal before, p. 527.

The jury found the prisoner guilty, and sentence was deferred.

Correspondence.

Appeal to the Benevolent.

Sir,—I must appeal to your kindness to give publicity to the following case of exceptional distress. For six years prior to 1872, a registered chemist and druggist was in business on his own account in Weymouth Street, Portland Place, when in getting out of a train at a station on the Great Northern Railway he and several other passengers were thrown down on the platform by a movement of the train after it had stopped. The immediate result of this accident was that his intellect became impaired and the business had to be given up. His wife, anxious to retain him at home, and hopeful of improvement, struggled on, having the best medical advice; the case, however, proved hopeless, and the poor wife's means having become exhausted, he was three years since sent to Hanwell Lunatic Asylum, where he now is. The only means of subsistence which his wife (now 55 years old) has is derived from letting lodgings, and 15*s*. a week for the board of her son who is assistant to a medical man. The case came before the Benevolent Fund Committee, at a meeting at which I was present, and it is from this source I derive my information. The Committee expressed great interest and sympathy in the case, and recommended the Council to make a grant to alleviate temporary pressing wants, but the means at its disposal would not allow of the grant of a sufficiently large sum of money to enable the poor woman to go into a court of law to recover from the Great Northern Railway Company compensation for her husband's injuries. Soon after the accident a claim was made on the Company, and Mr. (now Baron) Hawkins was retained to conduct the case, upon whose advice the damages were laid at £6000. The negotiation with the Railway Company, after extending over a considerable period, has now been brought to a close by a refusal to recognize the claim. The elevation of Mr. Hawkins to the Bench renders it necessary to engage fresh Counsel, and the payment of the necessary fees to bring the case into Court would require about £70. It is believed that if the necessary funds were forthcoming substantial damages might be obtained; and it is for the purpose of appealing to the benevolent, that I am induced to place the circumstance before the readers of the Journal. The wife has a most excellent character, and Mr. Holmes, of 158, Fenchurch Street, solicitor, has all the necessary papers and is ready to proceed with the case. Mr. Bremridge or myself would gladly receive any subscription forwarded for this object.

W. D. Savage,
Vice-President of the Pharmaceutical Society.
Brighton, Jan. 5, 1877.

The Hygienic Influence of the Pine and Eucalyptus.

Sir,—I have no intention of using your correspondence columns to discuss with Mr. Kingzett the results of the spontaneous decomposition of the aromatic hydrocarbons, still less of entering into a disquisition on the merits of Terebene as a deodorant and disinfectant. Those of your readers who may feel an interest in the matter may satisfy themselves whether Mr. Kingzett's depreciationy estimate of it is borne out by the experience of others by referring to your advertisement columns, where they will find abundant evidence as to its valuable properties. I think that I may fairly reply to Mr. Kingzett in the language of Shylock, that, "till he can rail that seal from off my bond he but offends his lungs," in "denying emphatically that its value as a disinfectant and deodorant has been established in any way."

Mr. Kingzett writes very dogmatically as to what he has "proved in the most absolute way," and as to his conclusions being "beyond discussion." Dogmatism of this kind is not an unfamiliar characteristic of discoverers, and may be pardoned on the score of their not unnatural enthusiasm for their own bantlings. It is evident that Mr. Kingzett is so wrapped up in the astounding novelty of his own "discoveries," that he is quite unaware that his inferences are by no means altogether in harmony with the conclusions of inquirers in other parts of the world who have established at least as good a reputation in science as he has.

I am not going to set my assertions as to the results of the oxidation of Terebene against his, as that would be a mere waste of your space, but will simply invite those of your readers, who have time to investigate the subject, to do so for themselves, when they will, I think, find that despite Mr. Kingzett's assertions to the contrary, there is evidence of the evolution of ozone which it is very difficult to gainsay. I will only add that if Mr. Kingzett's acquaintance with the properties of Terebene is to be inferred from the objection which he raises to it on the score of its inflammability, it must be of a very limited character. Terebene is inflammable, it is true, and so is coal, if it be thrown on the fire; but short of this it is scarcely possible to ignite either it or its vapour.

I am, possibly, not so ignorant on the subject of Mr. Kingzett's "discoveries" as he may think, and have my own opinion as to the merits as a disinfectant of the solution of camphoric acid in water, which, under the somewhat ambitious name of *Sanitas* he proposes to introduce to the public, and for which he has taken out a patent. If he had been speaking as a disinterested witness in the paper which has originated this correspondence I might have thought that his omission of all reference to Terebene was a mere oversight, and have taken no notice of it, but, as it was, I felt that I was justified, both in my own interests and those of your readers, in reminding him of his omission, and making my modest reclamation.

Francis T. Bond, M.D.

Milk of Sulphur.

Sir,—Much discussion has arisen upon the question, "What is Milk of Sulphur?" and, with your permission, I shall attempt to prove precipitated sulphur is really what the compilers of the old London Pharmacopœia meant, and not a mixture of calcium sulphate and sulphur.

I shall first quote from an old dispensatory printed in the first half of last century.

London formula.—"Boil flowers of sulphur in water with thrice their weight of quick-lime till the sulphur is dissolved; filter the solution and drop into it some of the weak spirit of vitriol: this will throw down a precipitate, which is to be washed in fresh parcels of water till it becomes insipid."

Edinburgh formula.—"Boil the hepar sulphuris, reduced to powder, in four times its quantity of water for three hours, adding more water if there is occasion; then filter the solution whilst hot, and drop into it spirit of vitriol till effervescence ceases; a powder will be precipitated to the bottom, which is to be washed with water and afterwards dried for use."

The method of making the lac sulphuris, we are told, from hepar is more expeditious, but the quicklime method, or London formula, gives the preparation a more saleable whiteness.

We are also informed that the whiteness does not proceed from the sulphur having lost any of its parts in the operation or from "any new matter superadded."

In regard to the Edinburgh method a suggestion is made to perform the ablution with warm water so as more easily to wash away the potassium sulphate lest it be added to the sulphur.

It will thus be seen that more than a century ago apothecaries were aware of the fact of contamination, and used the term "parcels of water" so as to get rid of acid and any other soluble matter.

Now, calcium sulphate is one of those salts which is as soluble in cold as in hot water, one part dissolving in about 460; and we can easily imagine the diligence with which such washings were practised, and the purity of the lac sulphuris of bygone days.

We are instructed that the medicine is nearly the same in both cases, *i.e.*, whether made according to the London or Edinburgh formula, and no one will affirm, I think, that the lac sulphuris prepared according to the instructions laid down in the Edinburgh form could by any possibility contain calcium sulphate.

This granted, we are told, concerning the lac made according to the London form, that it differed only in whiteness, and was on that account more saleable.

Again, "if the lac be melted with a gentle fire it returns into yellow sulphur again." Here we have the most positive proof that the lac was pure sulphur, and the sublimation of it was used as a test of its purity.

Calcium sulphate and potassium sulphate were not to be found in the well made lac, for if our forefathers were not acquainted with symbols, they evidently had good observation and exercised common sense.

We are told "if common sulphur be ground with alkaline salts and set to sublime, it arises of a like white colour (to lac) the whole quantity of the alkali remaining unchanged." This alone is sufficient to prove that if lac sulphuris made in 1720 contained any admixture some note or record would be given, and, if they experimented with common sulphur are we to shut our eyes and veil our senses to the fact that lac sulphuris was, like a spoiled child, petted and caressed, and remained a stranger to sublimation?

I opine, from the evidence produced, the universal answer will be "No."

Sir Robert Christison, in speaking of precipitated sulphur, says, "It has a pale greyish white colour, and contains some adhering water, but in other respects is identical with flowers of sulphur."

Dr. A. T. Thomson says, "Sulphur præcipitatum of the London College is stated to be that which is precipitated from the sulphuret of calcium by means of hydrochloric acid." . . . "It used to be called milk of sulphur, or lac sulphuris." . . . "It is very often adulterated; generally with sulphate of lime."

I think, Mr. Editor, I have proved that more than a century ago (1720) apothecaries were able to make and used a pure milk of sulphur, since the whiteness was not due to any new superadded matter, and the sulphur had not lost any of its parts. We are also told that it was not different in quality from pure sulphur, but was preferred in unguents, etc.

Coming down to recent periods, I have not been able to find any author who looks upon calcium sulphate otherwise than as something added. It is evidently an impurity, and was never intended to form 50 or 60 per cent. of milk of sulphur.

In regard to the sale of selenited sulphur I must leave you, Mr. Editor, to fight that battle; but, as a medical man, I should prefer the genuine precipitated sulphur.

I have examined a specimen of selenited sulphur, and the crystals are well formed, but no better drawings could be obtained than those, in 'Pereira,' 3rd ed., p. 345, of genuine and selenited lac sulphuris. The crystals are laminated to some extent, but many beautiful prisms are to be seen. In a specimen of genuine lac sulphuris no crystals are to be found.

A little of the lac may be moistened with water, and microscopically examined under a power of 50 or 320 diameters.

Geber, who lived in the 8th century, is supposed to have been acquainted with lac sulphuris, but how he prepared it I am at a loss to tell. One thing, I think, is certain, that sulphuric acid was not used in its preparation.

An interesting article may be seen in Dr. Thomas Thomson's 'Chemistry,' 6th ed., p. 287 (copied from Nicholson's Journal), "If common sulphur be sublimed into a vessel filled with the vapour of water, we obtain lac sulphuris of the usual whiteness, instead of the common flowers of sulphur."

As ordered to be prepared by the British Pharmacopœia, lac sulphuris should not be contaminated with calcium sulphate.

Pereira, Thompson, Royle, Neligan, and all our recent writers on materia medica, look upon the admixture of the lime salt as an adulteration.

I can see no advantage to the public in continuing to make an article according to an old form and not carrying out the instructions given, since in every respect the lac sulphuris of 1720, if properly washed, was precipitated sulphur, and equivalent to that of the B. P., 1867.

In the discussion of this subject there are many points left untouched, such as the various opinions as to the whiteness and therapeutic action of lac sulphuris.

I think, sir, I have touched widely enough this subject, and given so many authorities that the misty cloud of diversity of opinion amongst members of the trade as to what should be understood by the term "milk of sulphur," should now vanish.

Sulphate of lime is evidently an adulteration, and should not be found in milk of sulphur.

HY. BROWN, L.R.C.P., etc.

Northallerton.

[*** We think our correspondent is beside the question in discussing from a speculative point of view what should be understood by the term milk of sulphur. We have no doubt that precipitated sulphur is to be obtained, by those who desire it, of any chemist and druggist in the kingdom. But it is unquestionably the fact that very many persons refuse to accept the sulphur of the British Pharmacopœia as "milk of sulphur," but desire to have the preparation containing calcium sulphate, which is popularly known by that name. The only practical question, therefore, is whether a tradesman who supplies this article is to be treated as an offender against the law which prescribes a penalty for selling to the prejudice of the purchaser, an article that is not of the nature substance, and quality demanded by him.—ED. PHARM. JOURN.]

J. F. Williams.—We know of no standard by which to decide the knotty question propounded by you.

G. J. Gostling.—Four of the members are examined Pharmaceutical Chemists; the number of "Founders" would depend upon the meaning attached to the word and may be ascertained by referring to the Register. Notice of the nomination of a Member for election as a Member of the Council must be given in writing, disclosing whether such nominee be or not a Pharmaceutical Chemist, to the Secretary on or before the 24th of March. No form is provided. For details, see Calendar.

G. Dobson.—We are not aware that the chemistry that is the subject of the Cambridge University or other examinations differs in any respect from that science as taught in any of the numerous works on the subject.

"Acetum."—A recipe for toilet vinegar will be found in the number for May 6 last, p. 899.

COMMUNICATIONS, LETTERS, ETC., have been received from Mr. Lea, Mr. Porter, Mr. Abraham, Mr. Threadgale, Mr. Birkett, Mr. Williams, Mr. Fryer, Mr. Leay, Sirius, W. B.

NOTE ON DIKAMALI RESIN.

BY PROFESSOR FLUCKIGER.

The resinous exudation of *Gardenia lucida*, Roxb., a tree of the Rubiaceous order, is largely used in India, both externally and internally, as may be learnt in the Pharmacopœia of India, p. 118, as well as from the recent statements of Professor Dymock in the *Pharmaceutical Journal* for December 16, 1876, p. 491. This resin is well known throughout at least the southern and north-western parts of India under its Hindustani name, Dikamali.

Dr. Stenhouse* pointed out that it contains a crystallizable resin, gardenin—certainly, says he, one of the most beautiful substances of that kind. Dr. Stenhouse had apparently but a very old sample of dikamali at his command, which did not enable him to examine it so exactly as many interesting Indian products which that chemist has submitted to careful investigation. Nor am I aware that dikamali has ever been since noticed by any other chemist, with the exception of a strange confusion with crocin (or polychroit), the colouring matter of saffron. A similar, probably the same, matter has been proved to exist in the pods of the Chinese *Gardenia grandiflora*, Loureiro, as may be seen in Hanbury's 'Science Papers,' pp. 241 and 242. Curiously enough this colouring matter has been referred to the above crystals of gardenin isolated from dikamali, with which it certainly has not the least affinity.†

Having been supplied some years ago by my late friend D. Hanbury with a good sample of dikamali as met with in the bazaars of Bombay, I devoted the larger part of the small provision to ultimate analysis, and may be excused for communicating the results in this periodical, supposing that it might be of some use to any future observer. It would be well worth while to examine more exactly especially the fine yellow crystals of gardenin.

Dikamali, as before me, has a well marked peculiar strong odour, somewhat recalling that of rue, and at the same time of aloes; it is of a crystalline appearance and yellowish hue, the powdered drug displaying a decidedly fine yellow colour. By gently warming the drug with alcohol (0·830 sp. gr.) a large amount of adherent bark and wood remains undissolved; the solution of the resin is of a fine yellow colour, with a well marked greenish hue. It does not alter litmus paper, and assumes an intensely greenish brown colour on addition of perchloride of iron; on addition of a little soda it turns brown.

If dikamali resin is melted with caustic potash or soda an offensive odour, no doubt due to some volatile fatty acid, is evolved. I dissolved the melted mass in water, neutralized it with sulphuric acid, and caused the larger part of the sulphate of potassium to crystallize. The mother-liquor was shaken with ether, which by evaporation yielded a crop of crystals which I think are *protocatechuic acid.* They produced a fine greenish blue coloration with a dilute solution of perchloride of iron, turning red when bicarbonate of sodium was added.

* 'Proceedings of the Royal Society,' VII. (1856), 542.

† Gmelin, 'Chemistry,' English edition, vol., vi., p. 508, where Professor Kraut had already expressed that he doubted the identity of gardenin and crocin.

Dikamali resin consequently belongs to the *aromatic* class of organic substances.

I exhausted the resin with hot alcohol, about 0·830 sp. gr., which on cooling afforded a good crop of crystals of gardenin; a very small amount of them was further yielded by the mother-ley, which chiefly contained the amorphous part of the crude resin. The crystals were shown by the microscope to be still mixed with a little amorphous resin, from which I succeeded in purifying them by repeated recrystallization of the gardenin from hot alcohol. It finally consisted of yellowish acicular crystals, melting at about 155°C. Submitted to ultimate analysis by means of oxide of copper and chlorate of potassium, gardenin dried at 100°C. furnished the following results:—

I. 0·1968 of gardenin yielded 0·1158 of water and 0·4278 of carbonic acid.

II. 0·2006 of gardenin yielded 0·1232 of water and 0·4384 of carbonic acid.

III. 0·1255 of gardenin yielded 0·0768 of water and 0·2740 of carbonic acid.

Or, in percentages—

	I.	II.	III.	Average.
C	59·28	59·60	59·54	59·47
H	6·53	6·82	6·79	6·71
O				33·82

These figures would answer to the formula—$C_{23}H_{30}O_{10}$, viz.:—

23 C	276	59·23
30 H	30	6·43
10 O	160	34·34
	466	100·00

It was ascertained that the amorphous portion of dikamali dissolved readily in warm alcohol, and on cooling deposited but a few crystals of gardenin, accompanied by a very small amount of a flocculent matter, which was not further examined. The solution was filtered and mixed with an alcoholic solution of acetate of lead as long as it formed a yellow precipitate, P, which was separated from the liquid S, and washed with cold alcohol. P, decomposed by a current of sulphuretted hydrogen in a phial containing alcohol, afforded a solution which on evaporation yielded very little of an amorphous resin, too little for further examination. The solution S, after treatment with sulphuretted hydrogen, was filtered and evaporated. The residue consisted of a brownish soft resin, melting below 100° C. It was dried over sulphuric acid at ordinary temperature, then at 100°, and lastly at 112° C. By ultimate analysis the following numbers were obtained:—

I. 0·3606 afforded 0·2928 of water and 0·9700 of carbonic acid.

II. 0·2935 afforded 0·2451 of water and 0·7877 of carbonic acid.

Or, in percentages—

	I.	II.	Average.
C	73·36	73·19	73·27
H	9·01	9·27	9·14
O			17·59

From these results the formula $C_{23}H_{34}O_4$ may be calculated, although it does not answer very satisfactorily—

23 C	276	73·79
34 H	34	9·09
4 O	64	17·78
	374	100·00

It would appear from these results that the crystallized neutral resin called *gardenin* may be derived from the amorphous part of dikamali resin by action of oxygen, 4 atoms of hydrogen being removed from, and 6 of oxygen added to, the amorphous portion.

THE SPECTROSCOPE IN PHARMACY.

BY WILLIAM GILMOUR.

(*Continued from page* 571.)

The danger to which tinctures are subjected from exposure to sunlight has already been touched upon, but it may be necessary here to refer to it again for the purpose of pointing out one or two errors into which this very susceptibility to change on the part of the tincture may unwittingly lead us. In the first place, it need scarcely be pointed out that tinctures are unlike green extracts and dried leaves in respect that the source from which the latter are derived is only available once a year, and consequently age must always form an element more or less important, so far as the condition in which they may be presented to us is concerned. Age should not thus enter as an element, for consideration, into the case of the tinctures, for they may be obtained fresh and new at any time, so that if the leaves or other parts from which they are prepared have been carefully dried and preserved, the spectrum which they respectively yield should always be nearly uniform.

With this, however, should be taken the further important fact, namely, that unlike extracts and dried leaves, which are opaque and which, from the manner in which they are generally kept, probably suffer less from exposure to sunlight than from other causes already mentioned, tinctures suffer most from this cause. They are transparent and are frequently exposed to strong light if not to direct sunshine, so that they often change very quickly. In short, a tincture if new should yield an almost uniform spectrum, but if old, and especially if it has undergone some little exposure, it will most certainly have changed in nature to a greater or less degree. These facts have been forced upon my attention from having lately again read an interesting paper from the pen of Mr. Stoddart of Bristol, which appeared in the *Pharmaceutical Journal* (2 series, vol. xi., p. 132), on this same subject, and with more immediate reference also to these same absorption bands. My first impression on reading the paper referred to, was that Mr. Stoddart had been experimenting on tinctures which had undergone some exposure and which had in consequence changed in nature, for Mr. Stoddart not only failed to observe bands in tinctures yielding very characteristic spectra, but he also failed to note all the bands in other tinctures still which he examined. Probably, however, the dilution required by most of the tinctures to render them sufficiently transparent to admit of a proper spectral examination, examined as they apparently were with all their other colouring matters present, accounted also to a considerable extent for the missing bands. This will perhaps be more strikingly brought out if we make a classification of the different tinctures, not for any purpose of theorizing, but to admit of a ready means of illustrating the points contained in the foregoing remarks. Of the tinctures examined by Mr. Stoddart, and in which all the bands are not noted, may be mentioned, cannabis indica, digitalis, hyoscyamus, lobelia (æth.); and of those in which no bands were discovered, but which should have given characteristic spectra, lobelia, hop, senna. To this last class may be added, as closely resembling them optically in several respects, tinctures such as belladonna, buchu, conium, which Mr. Stoddart does not refer to in his paper. Taking then this rough classification, for it is nothing more, it will be noticed that the tinctures belonging to the first class are all of the kind more commonly used in pharmacy, and therefore not likely to be kept sufficiently long in stock to undergo great changes from exposure.

Moreover they are all deep-coloured tinctures, which, while requiring most dilution, if the other colouring matters are retained previous to examination, are at the same time least susceptible to active influence. In these circumstances it is not improbable that all the bands might be present in the tinctures and yet the more delicate be missed or removed entirely by the dilution. But whether removed or not no dilution can take place without altering the appearance of the bands and their relation to the age and general condition in which the tincture is presented to us. The advantage of separating and examining the chlorophyll apart from the other colouring matters present in the tinctures as already described will therefore be apparent. It not only avoids all uncertainty in the matter of their presence or absence, but what is equally important, it enables us to observe the precise condition in which they are present in the spectrum. Of the tinctures in the other class, the majority, it will be noticed, are of the kind not only less commonly used in pharmacy, and therefore for this very reason more likely to have undergone some considerable exposure, but they are also in most instances much more delicate in their actinic action. Senna probably is the only exception, but, strange to say, the majority of the commercial samples of this tincture which I have examined have exhibited no absorption bands whatever. It is certainly a tincture not used to any considerable extent, and therefore it is just possible that all the samples may have been of some age, but if it is kept in mind that the fresh tincture exhibits a very decided spectrum in which all the five bands are well defined and broad and moreover being very dark—darker than most of the other tinctures named—is not likely to be affected very actively by exposure, it must be considered more than probable that something else than mere age or exposure have to do with the change. The saccharine principle, or the acids of the raisins which enter into the tincture, both suggest themselves as elements predisposing to change, but the matter requires and should receive further investigation. In the case of the other tinctures of this class, of which belladonna, exhibiting as it does a very fine spectrum containing five well defined bands, may be taken as representative, exposure alone very soon changes entirely their appearance.

The decomposition of all the tinctures, it need scarcely be said, is in proportion to the intensity of the sunlight on the one hand, and the nature of the tincture itself on the other, but in the case of belladonna a few hours' exposure to direct sunshine will remove every trace of bands III. and

IV., reduce bands V. and II. to a mere shadow and considerably thin and narrow band I. itself, while the spectrum will probably elongate from about the beginning of the blue to the middle of it. At first this change is not observable by the naked eye, but by and bye the tincture will probably assume a cloudy appearance, which again clears on depositing more or less of a sediment. The tincture will then be found to have changed very perceptibly in colour, the peculiar dark olive green having paled and turned to a more or less bright rusty brown, and if the exposure be continued it is not difficult to recognize, in a short time, in some of the tinctures a marked change in both taste and smell. In this state many of the more delicate as well as powerful tinctures suffer much in therapeutic activity, and the probability is that all suffer in proportion to the susceptibility of the fresh plant itself to decomposition under similar exposure. In other words it is more than questionable if the spirit, though an extracting, be also a preserving agent of the active principle of the plant.

These details are dwelt upon, although to many they may appear somewhat insignificant, principally because so little is as yet known regarding those changes which take place from exposure in many of the tinctures, as also from the conviction that the sphere of the spectroscope, so far as they are concerned, will be less in the way of distinguishing individual tinctures thus in detecting the various stages of certain decompositions both interesting and important from a therapeutic aspect. As already stated the spectra of the different samples of tinctures examined, like those of the extracts, presented very great contrasts. So much was this the case that it was deemed prudent to prepare fresh tinctures in every instance for the purpose of examination, and the following may therefore be accepted as fairly representative:—

Tincture Belladonna.—Benzole solution, light olive green, all the bands visible; band I. broad and dark, band II. distinct but not very marked, band III. faint trace, band IV. resembling band II., and band V. broad and of some density, and all the spectrum absorbed beginning of blue. This tincture exposed for about a month during summer to diffused light of no great actinic power showed spectrum as follows: benzole solution very light olive green, band I. narrow and not very dark, bands II. and V. mere traces, bands III. and IV. wanting, and all spectrum absorbed towards middle of blue. Exposed for a month during winter the action was much less decided, band III. alone having disappeared, the others only thinning a little. In this and the other tinctures yielding any marked spectra, the solutions remaining after the chlorophyll had been extracted generally showed band I., but of no great intensity, and the addition of further benzole did not remove it. No other bands in any case were shown, and the solution itself was generally more or less of a rusty brown without any shade of green. Where the spectrum of the tincture was not very decided, as in the next instance, the solution showed no trace of band I. whatever.

Tincture Buchu.—Benzole solution light green, four bands only visible of which band I. was neither very broad nor dark; bands II., IV., and V. faint and none well defined, band III. being wanting. Buchu is a very good instance of a tincture in which the bands are rarely present in commercial samples.

Tincture Cannabis Indica.—Same as extract.

Tincture Conia.—Benzole solution very light bluish green, band I. only visible, which, though very decided, is of no great breadth; all spectrum absorbed towards end of blue. This tincture, prepared as it is from the fruit, is entirely exceptional, and the presence of undecomposed chlorophyll in the fruit may be taken as indicative of the condition in which it has been collected, dried, and preserved.

Tincture Digitalis.—Benzole solution very dark olive green, showing one of the finest chlorophyll spectra which it is possible to get. Band I. is very dark and broad, band II. very decided though narrow, band III. very distinct, band IV. broad and dark, and band V. of greater breadth and depth still, with a light shading previous to complete absorption of the spectrum. The whole of the bands stand out boldly, with considerable sharpness at the edges, so that a very good opportunity is afforded of noticing the effect of dilution and exposure, not only upon the individual bands, but upon the spectrum in general.

Tincture Hyoscyamus.—Benzole solution dark olive green. All the bands visible, band I. being broad and dark, band II. distinct but not broad, band III. faint, band IV. not very dark or broad, band V. of considerable breadth and well defined. All the spectrum absorbed towards end of green.

Tincture Lobelia.—Benzole solution light olive green showing four bands. Band I. dark and of some breadth, bands II., IV., and V. quite distinct but not presenting any special characteristics; band III. wanting, and all spectrum absorbed towards middle of blue. This spectrum was quite distinct from, and could not be mistaken for, the spectrum of the next tincture prepared from the same lobelia.

Tincture Lobelia (eth.).—Tincture full strength showed band I. broad and very dark, band II. of some breadth and quite decided, band III. faint, band IV. very decided, and band V. very broad and dark. The green and yellow of spectrum were somewhat changed in colour, and all was absorbed towards end of green. On diluting one half with ether the bands were very much thinned, III. being wanting; the spectrum was elongated and all the colours were much brightened.

Tincture Lupulus.—Benzole solution very light yellowish green, showing only band I. quite decided, but of no great breadth. All the spectrum absorbed towards end of blue with a considerable amount of shading.

Tincture Senna.—Benzole solution dark olive green, showing beautiful spectrum, containing all the five bands. This spectrum closely resembled digitalis, with probably the green of the spectrum a dirtier shade.

Such are a few of the preparations which advantageously may be subjected to an examination by the spectroscope. They are only a few out of many more which might profitably be brought under the scope of its investigation. Its application to fixed oils, for example, has quite recently been touched upon in the pages of the Journal, so that it need not again be referred to here, but probably a no less interesting and important sphere will be found in the examination of essential oils, than which no subject is more needful of investigation.

NOTE ON POTALIA AMARA.*

BY E. HECKEL AND A. HALLER.

Among the interesting plants growing abundantly in French Guiana, the *Potalia amara*, Aublet, notwithstanding the singularity of the properties attributed to it, has attracted but little attention from pharmacologists. The authors having had some well-preserved specimens in fruit placed at their disposal made some researches, of which they have published a preliminary report.

Aublet says of the plant that it is found only in the larger forests. All the parts are bitter. The young stems are sometimes charged with granules of a transparent yellow resin, which catches fire upon being exposed to a flame, and gives off an odour resembling that of benzoin. The leaves and young stalks are employed in tisanes as a remedy in venereal affections. The drink in a large dose is emetic, and some inhabitants told Aublet that it had been successfully used to empty the stomach in cases of suspected poisoning.

The authors, however, did not find that all the parts of the plant were bitter, having chewed both old and young leaves without perceiving any sensation of bitterness, however prolonged the mastication. On the contrary, the leaves possessed a very aromatic odour and taste, which were intensified in the stem bark and slightly attenuated in the root bark. The wood was aromatic, or but slightly bitter. From these observations the authors inferred that the emetic and bitter properties which Aublet thought were diffused throughout the plant were really located in different organs, and this inference was confirmed by the chemical examination.

De Candolle has remarked of these properties that this plant has the bitterness of the Gentianaceæ and the emetic action of the Apocynaceæ, and that, in fact, the genus *Potalia* is intermediate between the two families. This is an additional proof of the importance the natural affinities of plants have in the direction of pharmacological and therapeutic researches.

Fifty grams of dried and powdered leaves were boiled for fifteen minutes in three successive quantities of water, acidulated with sulphuric acid, strained, and the united liquors evaporated in a water-bath to a syrupy consistence; this residue was treated three times with 200 grams of hot 90° alcohol, the alcohol distilled off and the residue acidulated with a few drops of dilute sulphuric acid, and then treated several times with pure benzine to remove fatty matters. Finally, the residue, after being neutralized with magnesia, was exhausted with chloroform. The chloroform liquors when distilled yielded an amber coloured extract, which was excessively bitter, burning to the tongue, emetic in a small dose, soluble in ether, left no residue upon combustion, and gave with nitric acid a red colour passing to orange. The last reaction led the authors to suspect the presence of brucine, but they failed to get the characteristic violet reaction of that alkaloid with nitric acid and protochloride of tin, and the tests for strychnine were alike negative. From these first researches, therefore, it would appear that the leaves contain neither strychnine nor brucine, and that their emetic properties are due to a peculiar principle; this the authors hope to isolate when they obtain a larger supply of the plant.

Thirty grams of stem bark treated in the same way yielded a bluish-brown resinous extract, very bitter, partially soluble in acidulated water, and coloured red by nitric acid, but this colour was less intense than with the resin from the leaves. This product did not appear to possess emetic properties, even in largish doses, compared with the extract from the leaves. Of the latter a few milligrams applied to the tongue of a man quickly caused nausea, accompanied by a peculiar sense of strangulation. In further experiments the authors propose to modify the process so as to avoid the possibility of any alkaloid present becoming altered by the acidulated water.

* *Journal de Pharmacie et de Chimie* [4], xxiv. 247.

CULTIVATION OF THE CASTOR-OIL BEAN.*

The plant is a native of tropical countries, although it will grow almost anywhere in the United States. In northern latitudes it is an annual plant; but in the East Indies it becomes a tree, growing on from year to year, and attaining a height of thirty or forty feet. The same, to a greater or less extent, is true of the plant in Texas; but we are not informed how matters stand in Florida; it would depend, we presume, on the locality itself. The following is the mode of culture resorted to in southern Illinois: The soil is prepared first in the same manner as for corn, the ground being laid off both ways, seven feet apart each way. The planting is done in April, or as soon as the frost is out of the ground. Before planting, the beans are to be soaked from twelve to twenty-four hours in water about as warm as the hand will bear, when the seeds are first placed in the liquid. They are planted and covered like corn, two beans being dropped in each hill. They require about a week longer than corn to come up, and the sprouts, when they first appear, are of a red colour. Plough the land when the plants stand about three or four inches high, going close to the plants, leaving the middle of the row until you have gone both ways of the rows, and the beans have fresh loose earth around them. Then go through and clean the middle with a cultivator or a plough. When seven to ten inches high, the plants are to be thinned out so as to leave only one in a hill. When the plants average twelve to eighteen inches, they can take care of themselves, if the weeds are kept from the middle space between the rows. The fruits begin to ripen in August; a fair crop is from sixteen to twenty bushels to the acre. In California and in Texas, from thirty to fifty bushels. The beans weigh forty-six pounds to the bushel. As we have said before, the foregoing applies to the plant grown in southern Illinois; therefore allowance must be made for the difference of the climate of Florida, where it is proposed to cultivate it. The plants growing larger in warmer latitudes, will need to be set further apart; the crops will mature sooner and be more abundant, etc. In fine, various modifications will suggest themselves.

Gathering and Shelling the Beans.—The fruit is borne on spikes growing in the axils of the leaves and branches, and the seeds are enclosed in burs resembling those of small horse-chestnuts. They should be gathered as soon as they begin to turn from a red to a greenish-brown colour; for, on becoming ripe, the pods burst of themselves, scattering the beans ten or twelve feet in all directions. The best way to gather them is to draw a waggon along through each of the passage-ways between the rows, while pickers look over the plants on either side, gather all the clusters which are of the proper colour, and deposit them in the waggon, to be transported to a drying yard. The same operation has to be repeated every other day during the season. Each cluster contains from fifty to one hundred pods, and each pod three beans. The drying yard is prepared by levelling and rolling hard a piece of ground with a good southern exposure, and fencing it with boards to guard against the loss of beans when they "pop." The pods are spread thin, and occasionally turned. In case of rain, the spikes are raked up and covered, and the beans swept up. Sometimes it is found more advantageous to build a kiln or drying house, where artificial heat is applied. In these, the drying floor is about six feet above the ground floor, and is made of slats a quarter of an inch apart, so that on stirring the spikes the beans drop through the apertures and accumulate below. Whatever may be the process used for shelling the beans, they must finally be thoroughly dried and run through a fanning mill, or by some other means divested of all adhering dust or chaff. They are then ready for the mill or the market.

Expression of the Oil.—The oil is obtained in various

* From *The Druggists' Circular and Chemical Gazette*, December, 1876.

ways; but the process which gives the finest product is the following: The seeds are first shelled, then immediately crushed and pressed in hemp bags by a hydraulic press. The pressure must be gradually applied, as the oil is slow in running; but the shelling, crushing and submitting to pressure must be done as rapidly as possible, to avoid exposure to the air, which has the effect of colouring the product. The expressed oil is then heated with water in tinned vessels until the water boils, and the albumen and gum separate as a scum; this is carefully removed, and the oil, as soon as it has become cold, is filtered through canton flannel, and put into canisters. One bushel of good castor beans yields five or six quarts of oil.

REACTIONS FOR BENZOIC ACID.

The following list of reactions for benzoic acid is quoted in *New Remedies*, from a lengthy article, by Dr. Richard Godeffroy on the "Modes of Formation, Methods of Preparation, Properties and Reactions of Carbolic, Benzoic, Salicylic, Oxybenzoic and Parabenzoic Acids," which has appeared in the *Zeitschrift* of the Austrian Apothecaries' Society:—

1. On passing the vapour of benzoic acid over faintly ignited zinc powder, *essential oil of bitter almonds* is formed (Baeyer).

2. Benzoic acid, heated in a retort with coarsely ground pumice stone, splits into *benzol* and carbonic acid. If overheated, carbon is separated and naphthalin and pyrogenic oils are formed (Barreswil and Boudault).

3. On heating benzoic acid with a mixture of acid sodium sulphate and sodium chloride to 200° C., there are formed *benzoyl chloride*, hydrochloric acid, and normal sodium sulphate (Beketoff).

4. Benzoic acid is soluble in solution of sodium phosphates, which give up to it 1 or 2 atoms of sodium, producing thereby *sodium benzoate*. The solutions have an acid reaction, but give up benzoic acid on evaporation or to ether (J. Donath).

5. On mixing 3 mol. of benzoic acid with 1 mol. of glucose, and heating with a large excess of strong sulphuric acid, the liquid assumes a fine *blood-red* colour, which disappears after a while; finally the mass turns brown and black.

6. Aqueous chromic acid or potassium chromate and sulphuric acid do not alter benzoic acid, no odour of oil of bitter almonds is developed, and the chromic acid is not reduced (distinction from cinnamic acid).

7. A neutral solution of ferric chloride produces in neutral solutions of benzoates a flesh-coloured precipitate of *ferric benzoate* insoluble in water and acetic acid, but decomposed by hydrochloric acid, which produces free benzoic acid and ferric chloride.

8. Silver nitrate produces no precipitate in a solution of benzoic acid; but on saturating the free acid with ammonia a white crystalline precipitate of *silver benzoate* is immediately produced. This is soluble in ammonia, acetic acid and hot water.

9. Mercurous nitrate produces in a solution of bezonic acid a white crystalline precipitate of *mercurous benzoate*, very difficultly soluble in water. Alkaline benzoates produce a voluminous non-crystalline precipitate.

THE DETECTION OF ROSOLIC ACID IN PRESENCE OF MAGENTA.*

BY MM. P. GUYOT AND R. BIDAUX.

Rosolic acid, which dissolves in water with the colour of onion peel, possesses the property of communicating to wines the characteristic shade of old claret, We think it useful to make known at the present time the reactions which serve to detect it, either alone, or in presence of magenta. Some time ago we remarked that magenta is decolourized in presence of ammonia, and that ether removes from the mixture the colouring base, which may be reconstituted by the addition of an acid. In these conditions rosolic acid yields a characteristic rose tint and gives up nothing to ether. If we pour an acid into the rosolic solution, the shade of old claret is destroyed and gives place to a yellowish tint. If heated with gun-cotton, the rosolic liquor is fixed on the nitrogenized fibre, which, well washed and dried, takes a beautiful rose tint in presence of ammonia. This reaction may present itself in the course of the manipulations of an expert instructed to examine wines adulterated with magenta, and therefore it is well to mention it, for we must call attention to the fact it is the very opposite to what ought to be produced. We easily understand the embarrassment of the expert who, after having obtained gun-cotton or nitrogenized paper slightly coloured, expects to see the colour disappear on contact with ammonia, but perceives, on the contrary, a very vivid rose shade, which, instead of brightening under the influence of acetic acid, becomes yellow.

Into a flask containing ammoniacal rosolic acid, we poured sulphuric ether and then strongly agitated the liquid. After the complete separation of the two layers, the ethereal liquid was decanted and poured into another bottle. It was then limpid and colourless; we added to it pure acetic acid, which produced no change; the two layers separated and remained perfectly white. There was therefore no coloration, which shows that, in presence of ammonia, the ether does not remove rosolic acid. The inverse reaction is significant; rosolic acid, having become yellow under the influence of an acid, was treated as above with ether; the upper yellowish layer having been decanted, was submitted to the action of ammonia, which took a rose colour. If, in a flask, we put magenta with acetic acid, the rose tint does not change; ether added to this flask is coloured a violet rose. When decanted and treated with ammonia, there are formed at first two distinct layers, the lower one white and the upper ethereal, containing magenta. An excess of ammonia destroys immediately the coloration, and gives two layers perfectly colourless. It is important to remark that, whilst with magenta the ammonia renders the colouring matter white, with rosolic acid, on the contrary, the same alkali develops a rose shade, *which floats on the colourless ether*. Here, it is the *aqueous liquid* which is coloured, whilst if we acidify ammoniacal ether containing magenta, it is the ether, if in sufficient quantity, which takes the characteristic rose tint. There are then, in these comparative experiments, two very distinct reactions which can be made use of for the examination of liquids containing the two colouring matters. These reactions are shown in the table.

These reactions being well known, it is easy to separate from a single solution the two colouring matters. We pour into a flask the liquid to be examined; we add ammonia to it; we agitate with ether and then decant. In presence of acetic acid, the ether becomes coloured. This experiment can be checked by means of gun-cotton. In fact, if we saturate this nitrogenous matter with the decanted ether, it is changed into a gelatinous rose-coloured matter, with which we can obtain the reactions of magenta. As for the aqueous liquid, it may serve for a counter-test. The ammonia which it contains is driven off in the water-bath and we add acetic acid, which communicates the yellow tint mentioned above. If treated then with ether and ammonia, it is found in the desired conditions to furnish one of the reactions mentioned above.

It remains for us to know if, on submitting the mixed liquid to the action of acetic acid and treating with ether, we can separate the two colouring matters. They are both removed by ether, poured into an acetic liquid, which contains then yellow rosolic acid and rose-coloured magenta. When separated from the aqueous liquid, this

* From the *Comptes Rendus*, reprinted from the *Chemical News*, January 5, 1877.

coloured ether furnishes a very distinct reaction. A few drops of ammonia decolourize the ether and tinge the lower stratum rose colour, magenta disappears, and rosolic acid passes into ammoniacal solution. This process, as may be seen, differs very slightly from the former. The original treatment with acetic acid has for its object to render soluble in ether the two colouring matters, and remove them from the water in a more concentrated form. It requires only two manipulations, which, in certain cases of rapid determination is very important.

Gun-cotton	1. Ammonia	Decoloration	Magenta.
		Red coloration	Rosolic acid.
	2. Acetic Acid	Red coloration	Magenta.
		Decoloration	Rosolic acid.
Ether and Ammoniacal Solution	1. Ammonia	No action with either of these colouring matters.	
	2. Acetic Acid	Red coloration	Magenta.
		No action	Rosolic acid.
Ether and Acetic Solution	1. Ammonia	Ether, at first of a rose colour, becomes decolourized	Magenta.
		Red colouration of the upper layer	Rosolic acid.
	2. Acetic Acid	Ether coloured rose	Magenta.
		No action	Rosolic acid.

POISONOUS MATERIAL IN HAIR-DYES.*

It is right that the medical profession and the public should understand the poisonous nature of many of the preparations commonly sold as hair-dyes and hair-restorers. In spite of the Pharmacy Act, the sale of many active poisons is still, in this country, entirely unrestricted. It is true that arsenic, and a certain number of other common poisons, are under legislative control, and may not be sold retail unless properly described, and then only under certain conditions. But these provisions do not extend beyond a comparatively small number of well-known substances. Other poisons may be, and are, openly sold for domestic purposes without any warning of the risks attendant upon their misuse.

Such sale we hold to be dangerous, and morally wrong. Almost every day affords some example of the serious accidents which occur in households from the use of poisons, even when those poisons are properly described. When no printed warning is given, and particularly when the printed description is of such a nature as to lead to the inference that no poison is present, the danger is increased tenfold. Everyone knows the carelessness with which bottles are often treated in houses, and how apt ignorant persons and children, not to speak of those who ought to know better, are to make use of the wrong bottle. Even the word "poison," printed in large type, and the use of a peculiarly shaped bottle, are not found sufficient to prevent accidents altogether, and the sale of poisonous substances without any such warning ought, we think, to be prohibited in every case by law.

Many of the hair-restorers, or more properly hair-dyes, so extensively advertised and used, both in England and America, afford flagrant examples of the danger to which we allude. We have lately purchased and submitted to the independent analysis of two well-known chemists twenty-one samples of the preparations of this kind now in use in England, including, we believe, nearly all those which are best known, because most extensively advertised. The results of these analyses abundantly justify the remarks we have made, and we therefore present their main features to our readers. We of course take no notice of constituents, such as scent and glycerine, which have no significance in our present inquiry.

Out of the twenty-one examples examined, no less than fourteen were practically identical in their nature. They contained sulphur in suspension, and also lead in varying, but always in very considerable quantity. Three of these preparations bore American labels, the rest were English. The descriptions varied a good deal. Only one was plainly described on the label as poisonous if taken internally, while many were described as "perfectly harmless," "free from injurious substances," and so on. The prices varied from 1*s.* to 6*s.* per bottle.

Two more samples, one of them American, were found to contain lead and sulphur, but in a different form. The sulphur was present as hyposulphite, and, in fact, these preparations may be substantially imitated by adding hyposulphite of soda to a solution of a lead salt. A white precipitate first appears, which dissolves in excess, and the solution so obtained *does not give a precipitate with iodide of potasssium.* This is noteworthy, because in the handbill which accompanies one of the samples purchasers are warned against the dangerous hair preparations which contain lead as likely to lead to paralysis of the brain and insanity, and are directed to test all preparation with *iodide of potassium.*

In another sample, an American one, no free or loosely combined sulphur was found, but only lead in considerable quantity.

Another of the preparations was contained in two bottles, in one of which ammonio-nitrate of silver, and in the other pyrogallic acid, was detected. This, therefore, belongs to an entirely different class from the preceding.

The remaining three preparations analysed were intended for lightening, instead of darkening, the colour of the hair. No substantial difference between these samples was detected. Each was found to contain a tolerably concentrated and slightly acidulated solution of peroxide of hydrogen. It is well-known that this is the active agent in preparations of this kind. It can hardly be considered as poisonous, but its action on the hair is said to be injurious. The silly fashion which prompted its use is, we believe, dying out.

It will be seen that, out of the twenty-one samples examined, no less than seventeen contained lead. This lead was present, it must be remembered, not as a mere trace, but in most cases in large and deleterious quantity. In one sample, and that not the worst, we found five grains and a half of lead, equivalent to about ten grains of crystallized sugar of lead in each fluid ounce of the liquid.

A subsidiary question arises out of this inquiry which deserves the most careful consideration of the medical profession. Is it not possible that lead-poisoning may sometimes be produced by the incautious use of these preparations? Evidence upon the point is conflicting, and many physiologists hold that such an absorption through the scalp cannot take place unless the skin is broken. Taylor quotes a case to the contrary which came within his own observation, and many others of the same kind have been brought to our notice. But few, if any, of these cases are definitive, and real proof appears still to be lacking. It is, perhaps not likely that such poisoning very commonly occurs, if it ever does. In the majority of instances the liquid would probably be used with a certain amount of discretion, and would be applied mainly to the hair rather than to the head. But if the preparation were used incautiously, if the lead solution were rubbed frequently and in considerable quantity into the skin of the head, we are inclined to think that danger would exist. It would almost certainly exist if the skin were broken.

Many recorded cases show that very minute quantities

* From the *Lancet*, January, 13, 1877.

of lead may after a time produce symptoms of poisoning. Certain circumstances, moreover, induce us to think that incipient lead-poisoning is more common than is generally supposed. In all chemical laboratories the testing for lead in drinking-water is a common experience. The number of samples of water sent for this purpose is surprising. Now, in a great many instances no lead is found, and it is worthy of consideration whether in some of these cases the symptoms which threw suspicion unjustly on the water may not have been caused by the use of lead cosmetics.

The subject is a highly interesting one, and we shall be glad to receive evidence upon it from any of our readers.

NOTE ON SYRUP OF IODIDE OF IRON.*

BY H. F. MEIER.

Having formerly experienced some difficulty in preserving syrup of ferrous iodide from change, particularly when stored in bulk or in bottles only partly filled, I present below a method by means of which I believe I have overcome this trouble, at least to a very great extent. In deciding on the preservative employed, I was guided by a desire to avoid the introduction of any foreign elements—such as hyposulphites, phosphoric or citric acids or other materials—that would modify either the composition or its therapeutic action. In brief, the agent is iodhydric acid in a dilute form; and I find that an exceedingly small quantity is sufficient to prevent deposition of the iron contained in the preparation (generally as ferric oxide), and also the objectionable change of colour which occurs when the syrup is exposed to the action of the air, in consequence of the package being only partly filled, the latter change being due to the formation of ferric iodide.

The quantity I have used is equivalent to adding two grains of anhydrous acid to the pint of finished syrup, prepared according to the U. S. Pharmacopœia. I have a sample of syrup which has been standing for over three months protected in this manner, and it has suffered no change in colour, while being perfectly clear and free from sediment. As the medicinal effects of the preservative are the same as those of iodine, I can see no objection to it on this ground, while its other merits will, I believe, be substantiated by further and more extended trial.

As the usual way of preparing dilute iodhydric acid, by the decomposition of sulphuretted hydrogen with iodine suspended in water, is a very disagreeable one, I submit also a method by which it can be prepared, on the small scale, much more conveniently and equally as good for the purpose intended.

Dissolve 166 grains of potassium iodide in 2 fluid ounces of water, and 153 grains of crystallized tartaric acid in 4 fluid ounces of alcohol; mix the solutions, and when the precipitate (of potassium bitartrate) has subsided, filter, and wash the filter with a small quantity of 66°/$_{0}$ alcohol, and evaporate the filtrate to two fluid ounces. Each fluid drachm contains 8 grains of anhydrous acid, and this quantity should be sufficient to preserve at least 4 lbs. of syrup. This solution can also be used to redissolve the sediment in syrup that has decomposed in the usual manner—the above quantity being generally sufficient if time be allowed for the solution.

The best remedy for removing the colour after decomposition is without doubt the old method of immersing pieces of clean bright iron wire in the syrup, and agitating occasionally, as in this case the ferric is reduced to ferrous iodide; while in the case of exposure to sunlight, although this is an efficient bleaching agent, the probability is that the process is attended with the formation of ferric iodate.

The introduction of alcohol in the above formula for the dilute acid has for its object the complete separation of the potassium bitartrate, as I find that a fluid ounce of acid of the above strength is capable of dissolving about 35 grains of the bitartrate; consequently were water used in place of alcohol to dissolve the tartaric acid, the above proportion of salt would remain in solution and contaminate the product. In this respect the method which I propose differs from that of Dr. Buchanan.

A point very necessary to be observed is a prompt evaporation of the alcoholic filtrate to the required measure, for in presence of alcohol the acid decomposes more rapidly than in a merely watery solution.

On testing with hyposulphite of soda one sample that had been thus exposed for a day or two, I found 2 grains of free iodine in a fluid ounce, or about 3 per cent. of the anhydrous acid present. The acid, if preserved for any length of time, should be kept in bottles, quite full and well stoppered to exclude air.

My experience with this agent has not, so far, justified the supposition of Mr. E. D. Wayne, that free hydriodic acid would cause a deposit of grape sugar (see his remarks in the U. S. Dispensatory); and should any reader try this method, I shall be glad to hear a confirmation of the satisfactory results obtained.

* From *The Druggists' Circular and Chemical Gazette*, December, 1876.

THE USE OF SALICYLIC ACID IN THE HOUSEHOLD.*

BY DR. VON HEYDEN.

1. *Raw meat.*—It frequently happens, especially in warm weather, that meat, particularly such as contains easily decomposable fat and blood (tongues, etc.,) although otherwise irreproachable, upon closer examination or upon boiling gives off a disagreeable smell. This may easily be removed either by laying the meat before cooking in lukewarm water containing ½ to 1 gram of salicylic acid to the litre, or by throwing some small crystals of acid into the water during the boiling.

When it is desired to preserve meat for some days, it is recommended to lay it in a solution of salicylic acid in water, ½ to 1 gram to the litre; or to rub lightly salicylic acid into the meat, especially the bones and fat parts. The preservation, as well as the cleaning for the dressing, is done in the usual way.

Although meat treated with salicylic acid loses its red colour on the exterior, it undergoes no change internally. Moreover, it becomes tender with less boiling.

2. *Milk.*—Pure cow's milk, to which dry salicylic acid (not in aqueous solution) has been added in the proportion of ½ to 1 gram to the litre, curdles at the ordinary temperature after about thirty-six hours, retaining its properties, the cream separating and yielding butter perfectly.

3. *Butter* kneaded with water containing ½ to 1 grams of salicylic acid to the litre, or packed in cloths saturated in such a solution, remains good longer than usual. Butter that has already become rancid can be improved by careful washing with aqueous solution of salicylic acid (2 to 3 grams to the litre) and afterwards rinsing with pure water.

4. *Preserved fruits* (cherries, currants, raspberries, plums, apricots, peaches) may be prepared advantageously, by placing layers of fruit and sugar alternately, without water, in a not very wide-mouthed pickle bottle, strewing over them a pinch of crystallized salicylic acid (about ½ gram to a kilo of contents), closing the jar with parchment paper that has been steeped in solution of salicylic acid, and boiling the bottles in the ordinary way in a water-bath. Bilberries are best boiled without sugar, allowed to cool, filled into a narrow-mouthed flask, some crystallized salicylic acid strewn over, corked, etc. Fruit thus preserved has been kept in excellent condition during two seasons. Another method is to lay over the

* From the 'Handelsberichte' of Gehe and Co.

surface of fruit preserved in bottles, a closely fitting piece of blotting paper that has been steeped in a strong solution of salicylic acid in rum. Preserved gherkins may be similarly treated. For those preserved in vinegar and sugar (*Essiggurken*) the salicylic acid is boiled with the vinegar, and when boiled poured over the gherkins. For salt gherkins (*sauer gurken*) the acid, ½ to 1 gram to the litre, is added during the boiling; in other respects the preparation is as usual.

5. *Preserved Vegetables* and similar articles may also have a small quantity of crystallized salicylic acid added.

6. *Fumigations.*—Dry salicylic acid, volatilized from a hot plate, purifies the air and perfectly disinfects the walls of a closed room.

7. *Vessels, Corks,* etc., to which a disagreeable smell or taste attaches, are thoroughly purified, by washing in solution of salicylic acid.

The solutions of salicylic acid for the above purpose are best prepared by rapidly boiling the acid in water, in the proportion of from 1 to 3 grams to the litre, and leaving to cool. Any excess that then separates is fit for fresh use; or if stirred up and used in suspension causes a corresponding increase in the action of the solution.

THE FLUORESCENT MATTER IN ATROPA BELLADONNA.*

BY R. FASSBENDER.

The author publishes some further information respecing the blue colouring matter discovered by Richter. It is found in all parts of *Atropa Belladonna*, and is distinguished by its great permanence and the strong fluorescence which can be recognized even when extremely diluted. The author found it in all the commercial extracts of belladonna he examined; whether commercial specimens of atropa and its salts are free from this substance he is not in a position to say.

In order to show how extremely small a quantity of this substance can be distinctly recognized, the author crushed two unripe belladonna berries in some water, evaporated the liquor in a water-bath, treated the residue with alcohol, filtered, evaporated the solution and again dissolved the residue in water. The filtered solution, which perceptibly reddened blue litmus paper, was digested with animal black, which absorbed the colouring matter; the charcoal was treated with alcohol at a gentle heat, a few drops of ammonia added, the liquor filtered, and the charcoal again washed with alcohol. The filtrate was clearly fluorescent, and when diluted with 200 c.c. of alcohol, the characteristic blue colour was still distinctly perceptible if looked at from above. The great permanence of this substance may be shown with a few drops of a less dilute solution mixed with a drop of ammonia in a watch glass; after the rapid drying up of this liquid upon a warm day the reaction is reproduced by the addition of more ammonia. Besides the colouring stuff there is obtained by the above method of preparation a yellow resinous body extremely insoluble in water and very soluble in alcohol.

THE DIGESTIVE FERMENT OF NEPENTHES

The viscid secretion of *Drosera, Nepenthes, Sarracenia*, and other carnivorous plants, by means of which a function analogous to that of digestion by the gastric juice of animals is apparently performed, has already been made the subject of investigation by Mr. Lawson Tait, of Birmingham, Riess and Will, of Erlangen, and others. Mr. S. H. Vinnes, of Christ's College, Cambridge, has recently published† an account of an exhaustive series of experiments as to the nature of the secretion of *Nepenthes*, conducted at the Royal Gardens, Kew. The species experimented on were *N. hybrida* and *gracilis*. The pitchers of these plants, Mr. Vines treated just as though they had been the gastric mucous membrane of an animal, first with absolute alcohol, and then with glycerine. Taking three test tubes, he placed in the first a little of the extract and a few drops of dilute hydrochloric acid (0·2 per cent.), in the second, a little of the extract only, and in the third, some of the diluted acid; to each he then added a small piece of swollen-up fibrin, and exposed them all to a temperature of 40° C. At the end of eight hours he found that the fibrin in the first tube showed signs of the digestive action of the fluid, and the filtrate gave a distinct peptone reaction. The fibrin in the two other tubes was unaffected, and their filtrates gave no reaction with caustic potash and copper sulphate. This experiment appears to prove that the glands of the pitchers contain a digestive ferment which is soluble in glycerine, and which can exert its digestive action only in the presence of an acid; that, in fact, the solution of proteids by insectivorous plants is effected by a true digestive process, which resembles in every particular the process of solution of proteids which takes place in the digestive cavity of an animal.

The most recent researches on the digestive process in animals, appear to show that the secreting cells of the stomach do not directly secrete the digestive ferment, but that they give rise to a neutral substance, which has been termed zymogen, consisting of a combination of the ferment with (probably) an albuminoid. It is only when this zymogen is decomposed by the action of various agents (dilute acids, moisture, warmth, etc.), that the ferment is set free in the active state, in the gastric juice as pepsin, in the pancreatic secretion as pancreatin.

In order to obtain a more active glycerine extract than the one previously employed, Mr. Vines next treated pitchers of the two above-named species of *Nepenthes* with dilute acetic acid (1 per cent.), for twenty-four hours previously to the preparation of the glycerine extract, and instituted comparative experiments between the glycerine extract so obtained and that prepared in the ordinary way from pitchers gathered at the same time from the same plants. In every case he found that the digestive power of the former was much greater than that of the latter. For instance, he placed a pellet of swollen-up fibrin in a tube containing a small quantity of the acid extract, and a similar pellet in a tube containing the same quantity of the neutral extract. To each he added two cubic centimetres of dilute hydrochloric acid (0·2 per cent.), and exposed them both to a temperature of 40° C. At the end of six hours the fibrin in the first tube had undergone complete solution, while that in the latter had been but slightly attacked. The filtrates of both tubes gave the peptone reaction. These experiments seem to indicate that in the gland-cells of the pitchers of *Nepenthes*, as in the secreting cells of the stomach and of the pancreas, the digestive ferment exists at first in combination with some other body as zymogen; and that in plants, as in animals, this zymogen can be split up by the action of dilute acids, the free ferment making its appearance as a result of this decomposition. The experiments are, in fact, precisely parallel to those made by the most recent observers on the processes of digestion in the stomach and the pancreas.

Mr. Vines' results are in complete harmony with, and tend to confirm the accuracy of, those made by Riess and Will on the secretion of the leaf-glands of *Drosera rotundifolia*, and by Van Gorup Besanez on that of the pitchers of *Nepenthes phyllamphora* and *gracilis*. The latter experimenter found that shreds of fibrin placed in the secretion (which had an acid reaction) were more or less completely dissolved within an hour when exposed to a temperature of 40° C., and that the filtered liquid gave the characteristic peptone reaction with caustic potash and dilute copper sulphate. The digestive process was very much accelerated by the addition of a few drops of dilute hydrochloric acid (0·2 per cent.). The experiments on the secretion of *Drosera* gave precisely analogous results

The Pharmaceutical Journal.

SATURDAY, JANUARY 20, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, *17, Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary, 17, Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE CONSTRUCTION OF A PHARMACOPŒIA.

A SHORT time since, we referred to the fact that the question of Pharmacopœia revision, and especially that part bearing upon the qualifications of the persons who should be entrusted with carrying it out, was exciting considerable interest among medical men and pharmacists in the United States. On that occasion we quoted from some remarks made by Dr. SQUIBB before the Medical Society of the State of New York, and as he has since further developed his views at a "conversational meeting" of the New York College of Pharmacy, we take the opportunity of reverting to the subject.

In order to illustrate the formation of opinion on this question in the United States, it will be well briefly to refer to the history of the successive Pharmacopœias of that country. The first was published towards the close of the year 1820, under the authority of a "National *Medical* Convention" that met at Washington. Before breaking up, this Convention passed a resolution to meet again in 1830, which resulted in the publication of a Pharmacopœia of that date. The Convention met for a third time in 1840, and appointed a committee of seven medical men—in which Dr. WOOD acted as Chairman, and Dr. BACHE as Secretary—to superintend the revision and publication of the Pharmacopœia; it also authorized the Committee to request the co-operation of the Colleges of Pharmacy of the United States. Such assistance was accordingly asked and given, especially by the Philadelphia College; still the responsibility of accepting or declining suggestions lay with the *medical* committee, and the U. S. Pharmacopœia of 1842 was published "by authority of the National *Medical* Convention." But in the usual instruction to the President to call another meeting of the Convention after ten years, he was told to invite delegates from colleges of pharmacy also, and as a consequence two pharmacists were included among the committee of nine to whom the revision of the Pharmacopœia was then entrusted; the edition of 1851, however, was still published "by authority of the National *Medical* Convention. In 1860 the committee appointed appear to have consisted of four pharmacists and five medical men, and that of 1870, of seven pharmacists and eight medical men, and the resulting Pharmacopœias of 1864 and 1873 were both published "by authority of the National Convention for Revising the Pharmacopœia.

The approach of the time for the sixth decennial revision, and the alteration of the conditions under which the work was formerly done, has given rise to a discussion of the questions in whom the copyright should be vested, and by whom the work should be done. According to Dr. SQUIBB, the remuneration for the labour spent on former editions has been made in a very indirect manner. Dr. WOOD and Dr. BACHE, the editors of the well-known 'Dispensatory,' gave their labour to the Pharmacopœia with the effect of increasing the sale and giving authority to the 'Dispensatory' based upon it, and rendering the 'Dispensatory' one of the most successful medical books, in its financial results, ever published. For many years these two books, being revised mainly by the same hands, supplemented each other. But in 1864 Dr. BACHE died, and Dr. WOOD became too infirm for work, and since then no additions have been made to the 'Dispensatory;" so that in 1872 the U. S. Pharmacopœia had for the first time to stand alone, a test that in the opinion of some it did not pass satisfactorily. What is now desired is that future Pharmacopœias should contain within themselves not only a list of official articles, but methods of recognizing whether they agree with the standard. Thus with respect to rhubarb it is asserted that it is not sufficient to define it as the root of *Rheum palmatum* and other species of rheum, but that the physician and pharmacist wish for something to tell them how to select good rhubarb, and care less for the botanical species than for sensible properties and tests. It is also proposed that only articles of established reputation should have a place in the Pharmacopœia, a course that would probably do away with the "secondary list" that has been eulogized by some persons in this country. In order to replace this probatory section, however, it is suggested that an "annual fasciculus" should be issued, not having the standard force and authority of the Pharmacopœia, and that the opportunity afforded by quinquennial revisions should be utilized for inserting in the standard work those articles that survive this preliminary test.

This leads up to the important question, Under whose control is all this to be done? The United States is, we are told, a free country; too free to allow its Government to interfere in the way of giving authority to a Pharmacopœia as in the Old World nations. But one consequence is that if a medical convention were to bring out one Pharmacopœia, there is nothing but the possibility of unsuccess to deter a pharmaceutical convention, or any other body or individual, from publishing another. Dr. SQUIBB would give the control, so far as this could be done, to the medical profession, on the ground that pharmacy is only a part of medecine, like surgery or any other speciality, and that for pharmacy to claim that it should revise and control the Pharmacopœia, and invite medicine to join, as seems to be proposed by some American pharmacists, would be an example of a stream rising higher than its head. He goes so far as to say that "every pharmacist should be a member of the medical profession by education, and should then be a member of the American Medical Association." Holding this theory, which indeed he has himself reduced to practice, Dr. SQUIBB contemplates the Medical Association this year seizing Time by the fore-lock, and sending an intimation to the medical and pharmaceutical bodies represented at the last National Convention for revising the Pharmacopœia to the effect that it has decided to take possession of the Pharmacopœia, and invites them to send their next delegates with authority to transfer their allegiance from the Convention to the Medical Association.

Dr. SQUIBB's course would so thoroughly place the control of the United States Pharmacopœia in the hands of the Medical Association that it is satisfactory to find that this is only because he wishes it to become the *fons et origo* of authority on the matter. He proposes that the work should be done by a "Pharmacopœial Council" of five members, responsible only to the Association. According to his scheme, the Medical Association would elect only the President of this Council; then invite the Surgeon-Generals of the Army and Navy to appoint two members, and the American Pharmaceutical Association to appoint the other two. An expert chemist and pharmacologist, liberally paid, would be employed permanently on the work under the direction and supervision of the President. The Council itself would meet during the revisions once in three months, at other times less often, and the members would be paid in proportion as the increasing profits from the copyright of the work would allow.

In the discussion which followed Dr. SQUIBB's speech his views received considerable support. His proposition so fully recognizes that even if pharmacy be a subordinate section of medicine it is the section peculiarly adapted for such labours as the construction of a Pharmacopœia, and it goes so far beyond what has yet obtained in this country, that we do not presume to criticize it. But unfortunately in some remarks with which Dr. SQUIBB closed the discussion he thought fit to introduce an offensive element. He said that a point that was not to be lost sight of was that more than one half of the pharmacists were merchants only, and that there was always danger when mercantile interests controlled the materia medica. He considered that the influences of trade and of profits were the only ones to be feared, and as these would be always on the side of the pharmacists they should be in the minority for safety to the Council and its work. Unless United States pharmacists differ very much from their English brethren, the prospects of an amicable discussion leading to satisfactory settlement will not be promoted by such statements as these.

THE CHEMISTS' BALL.

THE eleventh annual Chemists' Ball was held at Willis's Rooms, on Wednesday last, with a success similar to that which has attended this gathering from its first institution. The single toast of the evening, "Success to the Chemists' Ball,"—with three cheers for the ladies—was given, in a short but effective speech, by Mr. WILLIAMS, the President of the Pharmaceutical Society, and was most cordially received. The music in the programme was well selected, and it is hardly necessary to say was excellently rendered by Mr. DAN GODFREY's band.

Three hundred guests were present, and their acknowledgments are due to the Committee for the perfect arrangements that were made, and especially should they be offered to Mr. CARTEIGHE, the Chairman of the Committee, and to Mr. WALTER HILLS, the Honorary Secretary.

FATAL RESULTS FROM THE USE OF CHLORAL HYDRATE.

THE death of Dr. MERCER, of Beverley, from chloral hydrate, recently, leads the *British Medical Journal* to remark that whilst in this and similar cases the responsibility of this compound for the fatal result has been amply proved, in many of them the evidence that an over dose had been taken was defective. Our contemporary points out that scientific opinion inclines to the view that chloral hydrate, when taken continously for some time, even in moderate doses, exercises a paralysing influence over the vaso-motor nervous system and leads to a failure of the heart's action. This effect may occur suddenly, without any serious warning, and it is thought not improbable that in some cases in which it has been assumed that because death supervened an excessive quantity of the drug had been taken the assumption has been groundless. It may have been that the ordinary dose had been adhered to, but that the cumulative weakness which its oft repeated action had induced, ended in the stoppage of the vital processes.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A meeting of the above Association will be held at 17, Bloomsbury Square, W.C., on Thursday evening next, January 25th, at eight o'clock, when a paper will be read by Mr. W. R. ATKINS on "Faraday."

WE regret to learn that with the December number, which completed the twentieth volume, the publication of the *Revista de Pharmacia e Sciencias Accessorias do Porto* ceased. It was the editor of this periodical, Senor ALBANO ABILIO ANDRADE, who a few months ago wrote a spirited defence of Portuguese pharmacy in an article which was reproduced in this Journal.

Transactions of the Pharmaceutical Society.

Provincial Transactions.

LIVERPOOL CHEMISTS' ASSOCIATION.

The sixth general meeting was held at the Royal Institution, December 21st, 1876. Mr. Joseph Woodcock, Vice-President in the chair. The minutes of the previous meeting were read and confirmed.

Several donations to the Library were announced and to the Museum a specimen of Chrysophanic Acid, prepared by Messrs. Symes and Co.

Dr. Symes said that the sample of chrysophanic acid was prepared about a year since from araroba by the method suggested by Dr. Attfield, viz., solution in hot benzole; but he had found that re-dissolving in alcohol, as recommended by Professor Attfield, was quite unnecessary, it neither improved the appearance or purity of the product. Most of his hearers had read Mr. Balmanno Squire's remarks on chrysophanic acid ointment, and probably had been struck by the impracticability of the process suggested for its preparation. But he held that as pharmacists they were greatly indebted to that gentleman for his letters on new preparations, and he thought other members of the medical profession would do well to take a hint from him, viz., in bringing before the pharmaceutical world early notice of the remedies desired to be introduced, and thus enable the dispenser to become familiar with them, and the method of their manipulation before he found them in a prescription.

The following paper was then read on—

FATTY SUBSTANCES AND COPPER.

BY JAMES T. ARMSTRONG, F.C.S.

In the *Chemical News* for October 27, November 10 and 17 of this year, there is the result of a well conducted series of experiments "On the Action of Different Fatty Oils upon Metallic Copper," by Mr. William Thompson, F.C.S. In his experiments he took pieces of copper foil and slips of metallic copper and placed these in a given quantity of different oils and kept them in this condition about ten months and noted the results, which in the manner in which he has published them are very interesting and may, if the subject is further pursued, lead to some important facts.

With a view to do what Mr. Thompson has done, viz., to study the action of copper on a fatty material, but not working so elaborately and spending only a little time on the subject just with a view of getting preliminary results, I placed a fat that I knew certainly contained copper on April 1st of this year (therefore, as you see, knowing nothing of Mr. Thompson's experiments) in a basin which had a cover but which was not air-tight. The fat was a spent railway grease, which when I put it into the basin looked like a very dark low grease, but had not the slightest appearance of containing any copper. The sample was quite uniform in its look in every way.

I have now brought a sample to show the strong action that has taken place. And what do we find? That the fat is completely coated, and very thickly too, with a green salt of copper. The grease being chiefly palm oil I will now compare it with the results obtained by Mr. Thompson with palm oil.

Appearance of Palm Oil when examined by Mr. Thompson.	Appearance of Spent Railway Grease when examined by myself.
No change appears to have taken place in the oil.	No change appears to have taken place in the grease (excepting the surface becoming coated with copper.

Appearance of Strip of Copper. By Mr. Thompson.	Appearance of Surface of Grease. By myself.
The strip is covered with a bright green deposit of copper salt; at some parts, however, the copper appears quite bright.	It is covered with a bright green deposit of copper salt; some parts, however, the grease appears as when put in basin.

The relative amounts of copper left in the grease and the acidity I am not able to tell, not working as Mr. Thompson did with many samples.

When we therefore take into consideration that many of the oils examined by Mr. Thompson did quite the opposite to what I have described his sample of palm oil to do, it is of some service I think to know that the oil placed in a different position, viz., mixed with a grease, will give the same results, for might not this lead to copper being used as a test for the mixture of some oils one with another or with a fat? Mr. Thompson, in his experiments with tallow oil, found it absolutely free from even a trace of copper, and presuming that tallow would act in the same manner if palm oil or palm grease be mixed with it, we have here most likely a good test for its adulteration with that article.

The chairman then called upon Mr. Alfred Clay Abraham to read his paper entitled:—

Notes on some of the Processes and Preparations of the British Pharmacopœia.

I must ask your forgiveness if I bring before you this evening, under the title of notes on some of the processes and preparations of the British Pharmacopœia, a number of disconnected facts, and deal with them in a manner which may be thought cursory. I have, however, endeavoured to bring before you some facts which I have thought tended to show that an alteration might with advantage be made in some of the processes. In the first place let me say a few words regarding the general manipulation of drugs which has I think in some respects been so much improved by our American cousins.

I presume that every one who has been practically engaged in making pharmaceutical preparations, has had a difficulty sometimes in knowing to what degree of comminution drugs should be reduced before being subjected to the action of solvents. Now there are two methods by which preparations of a definite strength may be obtained.

The first and the old method is maceration, which if properly conducted removes just that proportion of the soluble matter which is practically represented by the proportion between the quantity of menstruum used, and the quantity recovered. Now this method is, if carried out with the nearest approach to theoretical accuracy obtainable, viz., reduction of the drug to fine powder and long maceration, a very perfect one, because, whatever the product may be, it must always be of the same strength, provided of course that the drugs operated upon are of the same quality. This process, however, has the disadvantage of being both very slow and very extravagant, as of necessity, if say 10 per cent. of the menstruum remains in the marc 10 per cent. of the virtues of the drug are lost.

The newer process—viz., that of percolation—which has to so great an extent replaced maceration, relies upon a better principle—viz., the complete transference of the soluble, or at least the active portions of a given quantity of a drug to a given quantity of the menstruum. This latter process has, however, been a good deal abused, owing in a great measure to the fact that it has been misunderstood, and that the Pharmacopœia has, I think, given insufficient instructions for its conduct. It has been stated that the object of percolation is, that the menstruum shall *pass through* the drug, which expression is, I think, if in a sense correct, liable to a dangerous misconstruction. Now we can conceive a liquid entering a substance, dissolving its soluble ingredients, and *diffusing* out again, to be replaced by more liquid, but I think it is not conceivable that any liquid can pass through drugs. It is of great importance, I think, to observe the difference between *passing through* and *passing round*, because upon this depends the degree of fineness required, and also the tightness with which the packing should be conducted, for if the menstruum actually passed through the drug it must become saturated so rapidly that the time occupied in its passage would be of little importance; whereas, if it only passes round the particles the time occupied ought to be in proportion to the rapidity of the diffusion between the liquid actually absorbed and that only surrounding.

Now, does the P. B. take complete, or practically complete, exhaustion as its standard? for if it does not it is evident that it has departed from a definite standard in favour of an indefinite one, which I feel sure Professor Redwood would be the last authority to sanction. Here it has, to a certain extent, retained the old method, but I fear that by not giving definite instructions as to the fineness of the powders to be acted upon it has not attained so nearly to the standard of uniformity as it might. To obviate this objection, which has been pointed out so often lately, I would suggest that in our new Pharmacopœia (when one appears) there should be introduced a standard of fineness for powders similar to, but not identical with, that adopted by the United States Pharmacopœia. It might also, I think, be well to give to the term "slowly" a definite meaning by fixing approximately the time to be occupied by the passage of a certain amount of liquid—for instance, the quantity of spirit which should pass in the preparation of a pint of tinct. belladonnæ in twelve hours. Perhaps, also, it might be well to suggest or *enjoin* the use of percolators having a tap at the bottom, so that when necessary the flow could be checked or stopped at intervals.

I may say that I have convinced myself of the nicety with which comminution and time may be adjusted without either being pushed to an inconvenient extent, by finding myself able to exhaust some of our most bitter drugs so completely that the latter portions of the percolate and the pressings were so free from matter in solution as to be indistinguishable by taste from the pure menstruum.

I should also like to have the opinion of the meeting as to whether the introduction of the sp. gr. of oils, fixed and volatile, tinctures, etc., would not be of great practical value, and perfectly appropriate in a national Pharmacopœia.

I will now, with your permission, mention verbatim a few preparations which have been a source of difficulty to me and perhaps to others.

Acid. Sulphurosum.—Many of the gentlemen present, have no doubt experienced the difficulty, and practically, the impossibility, of making and keeping this preparation up to the Pharmacopœia standard. Now, if it is desirable to have a strong solution of H_2SO_3 on account of its oxidizing proportionately more slowly, then I would suggest the addition of a sufficient quantity of spirit to enable a 10 per cent. volume to be easily made and kept.

Cera Flav.—I hesitate to mention this subject in the room where it was so fully treated by one of our ablest members on a former occasion. But I may mention that of four samples of wax prepared by myself from the comb, I found the melting points to be 144, 146, 144, and 142 respectively. The B. P. defines wax as the "prepared honeycomb of the hive bee," whereas I think it would be more correctly defined as "the substance deposited by the hive bee as a seal to the cells of the honeycomb." The honeycomb is far from being wholly or even principally wax. Looked at with the microscope it is seen to consist in a great measure of pollen grains, which are probably the chief ingredient of the bee bread, and are also thought to be the source of the flavour.

Emp. Cerati Saponis.—How is it that the ingredients of this preparation which, according to the London Pharmacopœia of 1851, formed a cerate, form a plaster in 1867 simply by losing a little more water? If any gentleman can explain this apparently strange phenomenon he would at least do me a favour.

Emp. Plumbi.—Why are glycerine and other impurities left in this preparation? Is it on account of any advantage derived from their presence, or is it from the supposed difficulty of separating them. I have myself found the plaster separate almost completely by allowing it simply to cool sufficiently slowly without it being stirred after the combination has taken place.

Ext. Cinch. Liq.—After trying several processes for the manufacture of this preparation I have fixed upon the following as the best. The powder having been passed through a sieve of about twenty meshes to the inch is packed tightly in a stoneware or metal percolator, boiling destilled water is poured on, and that which remains on the surface is kept at the boiling temperature by passing into or through it a jet of steam. The process is continued, allowing the percolate to fall into the evaporating pan until exhaustion is complete. The liquid will require filtration before evaporation has reduced it to a very low bulk, as hot water dissolves more of the cinchotannic acid and cinchona red, etc., than cold, but as I think the solubility (or perhaps I should say diffusibility) of the alkaloids is increased in an equal or increased ratio this advantage may be disregarded.*

* The difficulty being as I take it not in the want of solubility of the alkaloids in their natural state of combination, but merely in the difficulty of reaching them without removing the substances surrounding them, which are so insoluble in cold water.

Glycerinum Acidi Carbolici, Glycerinum Acidi Gallici, et Glycerinum Acidi Tannici.—The Pharmacopœia directs these to be made by first rubbing them together in a mortar, and afterwards heating them in a porcelain dish. All that I have found necessary is to place the ingredients in a jug or convenient vessel in a water-bath, and stir for a short time until dissolved. This is of course of little importance, but many might go out of their way to adhere to the letter of the Pharmacopœia.

Liq. Antim. Chlor.—I have only to say that this preparation as it is found in the market is often much below the sp. gr. given in the Pharmacopœia.

Liq. Fer. Perchlor. Fort.—Various experiments which I have made have led me to the conclusion that a modification of the process in the United States Pharmacopœia is the most convenient, and obviates the consequences (sometimes very disagreeable) of the great violence which often accompanies the peroxidation when the solution has become saturated with nitric acid and the evolution commences. I find that if the nitric acid (or a portion of it) is added to a part—say a third, of the ferrous solution, that the excess of nitric acid easily and rapidly peroxidizes the iron, and causes the nitric oxide to be evolved, and that the heat generated by the gradual addition of the remaining ferrous solution is sufficient to cause the evolution to proceed in a regular, and therefore, controlable manner. Any nitric acid withheld may now be added, although I think the Pharmacopœia might add the words "so long as effervescence is caused," the quantity of HNO_3 ordered being excessive. This method I prefer to that of the United States, because unless such a temperature is maintained as shall cause the immediate evolution of gas upon the addition of the nitric acid, a point will be reached when a sudden evolution must take place.

In conclusion I must remind you that these few notes (to which I had hoped to add several others) are merely the result of observations and experiments made during the course of laboratory work, and are only put forward as the conclusions of one where the experiences of many are necessary for the attainment of the desired perfection, and I am sure that Professor Redwood, the distinguished editor of the Pharmacopœia, would be the first to acknowledge that it is only by contributions from all quarters, and their free discussion, that our national Pharmacopœia, which already bears so favourable a comparison with similar works, can attain this object.

At the close of the paper a lengthy discussion took place, the Chairman, Dr. Symes, Messrs. Armstrong, Davies, Tanner, the Secretary, and others taking part; and with a cordial vote of thanks to Mr. Abraham, proposed by Dr. Symes, seconded by Mr. Alfred E. Tanner, the members adjourned.

OLDHAM CHEMISTS AND DRUGGISTS' ASSISTANTS AND APPRENTICES' ASSOCIATION.

The annual meeting of the above Association was held at the Church Institute on the 3rd inst. The President, Mr. John Taylor, occupied the chair. After the usual preliminary business the chairman called upon Mr. J. Naylor, the Honorary Secretary, to read his report for the preceding year. In complying Mr. Naylor stated that in placing before the members his report of the transactions of that Association for the past year, it gave him very great pleasure to be able to certify that the condition of the Association was most satisfactory, a fact which he ventured to say would be welcomed by all, and the progress made during the year was most encouraging, considering what it had been previously. During the year the Association had succeeded in getting a room for the entire use of its members, which had been converted into a Laboratory, Museum and Meeting Room, in which there was a very good bench with necessary apparatus for conducting experiments in chemistry and pharmacy. It was also in possession of specimens of the whole of the

British Pharmacopœia preparations, thus affording every facility to its members for the passing of the examination of the Pharmaceutical Society. The Museum comprised between five and six-hundred specimens in a good state of preservation. The Association had also been indebted to the following firms for specimens, apparatus, etc., viz., Messrs Barron, Squire and Co.; Messrs. Langton, Edden and Hicks; and Messrs. S. Maw, Son and Thompson, London; Messrs. Evans, Sons and Co., Liverpool; and Messrs. J. Woolley, Sons and Co., Manchester; also to the Pharmaceutical Society for the weekly issue of the Journal, and to Professor Attfield, of the Pharmaceutical Conference, for the 'Year-Book of Pharmacy.' It was also a gratifying fact to know that all the principal chemists of the town had in furtherance of its objects willingly allowed themselves to be enrolled as honorary members, without the aid of whom the Association could not have advanced so rapidly. During the year there had also been some very valuable lectures, essays, papers, etc., given on the following subjects, viz., 'Forms of Crystals,' and 'Certain Manufacturing Processes in which Carriers of Oxygen are concerned,' by Mr. A. N. Palmer, M.P.S., of Manchester, and formerly of Bloomsbury Square, London. These lectures were deserving of special mention, Mr. Palmer very kindly coming from Manchester to give the same; apart from that the lectures were of a very superior kind. 'Adulterations of the Materia Medica of the British Pharmacopœia,' 'Elementary Botany,' 'Inflorescence,' 'Alcohol and its Allied Bodies,' 'Materia Medica,' 'Mercury,' 'Citrates and Tartrates,' 'Acetic Acid, Acetates and Lead,' 'Magnesium and Zinc' and Bromides, Chlorides and Iodides,' by Mr. W. H. Burrows; 'Adulterations of the British Pharmacopœia,' 'Potassium, Sodium, and Ammonium,' 'Practical Dispensing,' 'Iron Salts,' 'Arsenic and Antimony,' 'An Introduction to the Acids' and 'Magnesium and Zinc,' by Mr. John Wood; 'Animal Structure,' Chemical Analysis,' and 'Life, History, and Classification of a Plant,' by Mr. H. Hurst; 'Quinine,' by Mr. G. Hunt; 'Scammony and its Preparations,' by Mr. H. Critchlow; 'Glycerine,' by Mr. T. Pennington; and 'Doses of the British Pharmacopœia,' by Mr. L. Watson. In addition to the above, examinations had been conducted periodically; there had also been a class held on Monday and Thursday evenings, on the various subjects specified in the examinations of the Pharmaceutical Society. It would be unjust to conclude the report without reminding the members that it was probable the Association would lose one of its best members in a very short time, a fact to be regretted by all, as Mr. Burrows contemplated leaving the town; however, if such was the case, the energetic manner in which that gentleman had worked in connection with the Association would no doubt make a lasting impression upon its members.

The Treasurer (Mr. W. Hurst) then read his financial statement, which showed that the expenditure during the year had been exceptionally large, owing to the furnishing, painting, etc., of the room; notwithstanding this the accounts showed that there still remained a small surplus. A hearty vote of thanks was then given to the retiring officers, after which the election of officers for the ensuing year took place, and resulted as follows—President, Mr. John Taylor; Vice-President, Mr. John Wood; Treasurer, Mr. Walter Hurst; Librarian, Mr. Robert Thatcher; Secretary, Mr. Joshua Naylor.

The President, Mr. John Taylor, then gave his inaugural address as follows:—

Gentlemen,—Allow me to return you my warmest thanks for placing confidence in me by re-electing me President for the ensuing year, assuring you that nothing shall be wanting on my part in the furtherance of the objects of this Association. It is now seven years since this Association was established, the first meeting (called by advertisement) being held at the Waverley Hotel, in January, 1870, and in response we had most of the assistants and apprentices of the town and neighbourhood present to consider the advisability of forming an Association having for its object earlier closing, and to provide for its members a better system of education and mutual improvement for the various examinations required by the Pharmaceutical Society. At this meeting officers were elected, and all present gave in their names as members, which was very satisfactory. The first subject which your Association took in hand was "earlier closing," and in that direction it had been somewhat successful, the hours of business being much shorter now than they were then, which I am sure is a great boon to us all, giving us more time for study and recreation, and making us more fitting for the next day's business. It then took into consideration the forming of classes for the study of chemistry, pharmacy, materia medica, and Latin, which were very well attended and of great assistance to the members in preparing for their respective examinations. Three years passed over very pleasantly, when from some cause the members became lukewarm, owing, perhaps, to its officers passing their examinations and commencing business, which left the Association rather awkwardly fixed. This state of things lasted for two years but the Association still had an existence, and in 1875, when the time arriving that some of the members thought of going in for their examinations, it put a little more energy into the society, and it was reorganized, and I believe since then it has advanced more rapidly than in the whole time of its existence. From the commencement we have been greatly encouraged by masters who have given us every assistance, not only by the shortening of the hours of labour, but latterly by becoming honorary members by payment of an annual subscription. It has been a great help by placing means at our disposal by which we have been enabled to rent a room for our exclusive use, which has been fitted up with every convenience for the students, as mentioned in the Secretary's report, and I feel assured it will be taken advantage of by the members. In conclusion, I trust the coming year may be a successful one to this Association.

Proceedings of Scientific Societies.

PHILADELPHIA COLLEGE OF PHARMACY.

The third meeting of this College for the present session was held on the 19th December, under the presidency of Mr. Dillwyn Parrish. The first paper read was by Mr. R. V. Mattison on Diluted Phosphoric Acid, in which he described a process for its manufacture that he claimed to be rapid and safe in execution without requiring any special apparatus. The paper will be printed in a future number. Professor Maisch then read the following paper on—

THE USE OF PETROLEUM BENZIN IN PHARMACY.

BY L. WOLFF.

Petroleum benzin has been frequently proposed and variously experimented with by different operators, with the view of substituting it for the much higher priced ether in preparing oleoresins, and has been repeatedly found not to answer the purpose intended for it. Although its valuable solvent powers for fatty matter, wax and essential oils cannot be disputed, it fails to extract the resins and the active ingredients, which are of the utmost importance in oleoresins. Ginger treated with benzin yields an oil containing all the odoriferous properties thereof, but none of the pungent-tasting resin for the remedial properties of which it is justly celebrated, and which subsequent to the benzin process is readily dissolved from it by ether or alcohol. Buchu under like treatment, as reported by another contributor on this subject, gives an oily substance devoid of the diuretic properties of the leaves, though possessing their specific odour. Cubebs, though completely exhausted by benzin of its fixed and essential oils, fails to yield its cubebic acid to it, black pepper its piperin, and wormseed its resin and santonin; but all of the mentioned substances, and many more which have been subjected to the same process, are readily deprived of their fixed and essential oils, leaving them inodorous, seemingly dry and incoherent powders, that are, if treated with alcohol, ether or chloroform, readily deprived of their resins, thus affording a method for obtaining them separate from wax, fixed and essential oils.

Its extraordinary solvency for essential oils destines benzin for an important place in pharmacy, and oils derived by its aid from cinnamon, cloves, and other drugs are, if their odour is any indication of their value, if not superior, certainly not inferior to the distilled oils of these articles.

The oils obtained by exhaustion with benzin and its subsequent evaporation are mixed with wax and fixed oils to some extent, which can easily be separated therefrom by dissolving in alcohol, in which the latter are insoluble, filtration of this solution, and either expulsion of the alcohol by evaporation at the moderate heat of a water-bath, or much safer and better, by mixing the filtered alcoholic solution with several times its bulk of water, when the essential oil will arise to the surface or subside beneath it, as its specific gravity may be.

The oils by this cold process have a beautiful aroma, superior to many of the distilled ones, and the easy manner of obtaining them may, without doubt, prove a valuable method for the pharmacist who cannot always procure in the market the oils he wants, and has no facilities for distilling them, besides giving him fair means to arrive at a quantitative estimate of the essential oil contained in an article under analysis.

The essential oil of parsley seed cannot thus be separately prepared by the aid of benzin, as it contains another peculiar oily substance, well known by the name of "apiol," which is soluble both in it and in alcohol.

A great deal of the apiol in the market, both in bulk and in capsules, is nothing more than an oleoresin of parsley seed, which can lay no claim whatever to its name, being of green colour, insoluble to a large extent in alcohol, and congealing at ordinary winter temperature, all of which properties "true apiol" does not possess. Apiol has come into extensive use of late years, secured high praise as an emmenagogue, and is also claimed by its discoverers to be an antiperiodic but little, if any, inferior to quinia; but its high price, consequent to the expensive process as proposed by Messrs. Joret and Homolle perhaps, more than anything else, prevents its general introduction.

Powdered parsley seed, exhausted with benzin, and the liquid spontaneously evaporated, yields a mixture containing principally fixed oil, wax and apiol; the latter alone being soluble in alcohol can readily be recovered therefrom by repeated washings in stronger alcohol. The washings evaporated over the water-bath with a gentle heat, leave as residue "true apiol," corresponding in every respect with the article sold under the name of "Joret and Homolle's," having the advantage of its low price making it accessible to persons of limited means, as well as to the more favoured by fortune, especially if it is not dispensed in capsules, for which there is no occasion, since it may be given dissolved in essence of peppermint, or in emulsion, disguised by the oil of the same name. Samples of "apiol" prepared in this manner, have been tried by several prominent physicians, in their practice, and were pronounced to be equally as efficient as the imported French article.

Quite frequently the fixed oils much encumber the result of the pharmaceutical operations, as is prominently the case in preparing the "alcoholic extract of nux vomica," which has often been noticed and given attention to by many writers. Nux vomica, if exhausted with benzin, yields a large percentage of a clear fixed oil, congealing at ordinary winter temperature, and the powder, if subsequently treated in the usual manner with stronger alcohol, gives an extract which offers no trouble by proper evaporation in reducing it to the dry state. The oil derived from the benzin exhaust, to make sure of not losing any strychnia or brucia that may be contained therein, should be repeatedly shaken with dilute alcohol until the washings fail to betray to the palate the specific bitter taste of their alkaloids; then the washings must be mixed with the extract in course of evaporation, and the whole reduced to proper consistency. By the ordinary way, the separation of the oil from the extract is at best a tedious matter, causing the loss of extract, and is never completely performed, thus preventing evaporation to dryness, which by the benzin process is readily effected.

Another article, which the pharmacist has frequently to purchase at an exorbitant price, is "purified oleic acid," which has been much used of late in making the oleates now in use, and can be easily and at small expense prepared with benzin as solvent, in the following way:—

Oil of sweet almonds, saponified with caustic potash and the soap decomposed with tartaric acid, is washed with hot water to separate the precipitated bitartrate of potassium from the mixture of oleic and palmitic acids. These are combined with litharge forming the oleomargarate of lead, from which the benzin dissolves the oleate of lead, leaving as residue the undissolved palmitate thereof. From the benzin solution the lead is precipitated by dilute hydrochloric acid in form of chloride of lead, and on evaporation of the benzin "oleic acid" will remain sufficiently pure for pharmaceutical purposes, giving clear and permanent solutions with the red and yellow mercurial oxides, as high as 30 per cent. if necessary.

As crude commercial oleic acid can be bought at very low figures it may be purified by combining it with litharge, deriving from it the oleate of lead, from which again, by the aid of benzin, the purified oleate can be separated, and as before stated, purified oleic acid prepared at but a small expense.

To gain the same end the simplest way, perhaps, is to utilize the ready-made oleo-palmitate of lead, the officinal lead plaster, dissolve it in benzin and extract from it the oleic acid by precipitating the lead by aid of hydrochloric acid.

Oleic acid thus prepared has been used for some time, and found to answer better for the preparation of the oleates than the article sold by some of the manufacturing chemists.

The above results by no means limit the utility of petroleum benzin as a solvent and important pharmaceutical factor, but they will show that this refuse article, of comparative little commercial value, which has been applied to but little more than the removal of oil, grease or paint stains, may be turned to good account by its very deficiency to act like ether or similar substances as a general solvent for both fats and resins.

Professor Maisch regarded this as a very interesting subject, and one which was by no means exhausted. Some time since he had presented to the meeting styracin made of the use of petroleum benzin, and other observers had borne testimony to its manifold uses. Mr. William L. Harrison found in it an easy and cheap way of obtaining cinnamic acid, besides styracin, and Mr. Wallace Procter had separated with it a white crystalline substance from *Magnolia tripetela*. It was an excellent solvent for monobromated camphor and other crystalline bodies, and afforded a ready means of obtaining them in good crystallizations.

Professor Remington said that an odour of kerosene might remain in such preparations from the employment of a petroleum benzin which had not been carefully rectified

Dr. Pile said in preparing some oleoresins he had used the kind known as gasolin, and did not find any odour remaining.

Professor Maisch exhibited quinine flower, so called, and said that from experiments made by Mr. T. Beckert it was possible that it might contain an alkaloid; if so, it would be the first found in the Gentianaceæ. Mr. Beckert observed that the tincture evaporated, thrown into water, slightly acidulated and filtered, would yield a slight precipitate with Mayer's solution.

Dr. J. Dabney Palmer, of Monticello, Florida, had sent the quinine flower and its tincture; also tincture and fluid extract of buttonwood (*Cephalanthus occidentalis*) and tincture of *Sarracenia flava*, or trumpet plant, which appeared to be employed medicinally in that section of country.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

At the meeting of this Association on the 11th inst., the following paper was read:—

The Hieroglyphics or Signs Used to Decorate the Show Bottles of the Pharmacist.

BY J. H. HUGILL.

The abbreviation of words, by signs or hieroglyphics, in order to prevent their frequent repetition (a good example, for instance being °/ₒ for "per cent.") is supposed to have been introduced by the Arabians, and it is very probable that the alchemical signs used by the ancient alchemists were originally derived from the same source. In some ancient works they are very numerous and complicated, more especially those that occur in the writings of Bergmann. In a great many cases each writer used signs of his own, *i.e.* devised signs and terms for his own private use, or at least they were very far from being universal; and on account of their complexity they must have been very perplexing, for the great endeavour in those times seems to have been to render everything as hidden and difficult as possible to inquirers into chemical research, rather than to help in any way and make matters as simple as possible. This is more easily understood, when we consider that alchemy, translated, means "the hidden art," alchemists being those who practised this art; and not to have kept their knowledge a mystery would have been to make everybody equally rich; hence their great amount of secresy.

As before stated many of these signs were so complicated as to render them comparatively useless, but many of the commoner ones were universal, and frequently used to decorate the pharmacists' show bottles of the present day indiscriminately, and without any reference to their meaning. Amongst the most common of these ancient signs are the following:—

A circle with a dot in the centre ☉, intended to represent the sun. In chemistry it stood for gold, this being the brightest of metals, as the sun is the brightest of the heavenly bodies; but in some works it also represented Sunday—Die Solis—*i. e.*, literally, the day of the sun, hence the derivation of the word. It was, doubtless the anxiety and great aim of all alchemists to discover this metal, from any and every source, which led to the discovery of most of the others; as in searching for gold or traces of it (even when traces of its presence failed), other elements were discovered, up to that time unknown, and the knowledge of alchemy advanced step by step.

Silver was represented by a crescent or moon-shaped figure, ☽. The ancients, probably saw some analogy between the pale light of the moon and the well-known bluish-white lustre of silver; and even at the present day we hear of people speaking of the "silvery light," meaning moonlight; hence the representation of silver by this sign in former days, was far from incorrect. Lunar caustic is another term bearing on the point. The sign also stood for Monday—Die Lunæ. Thus the sun and moon, two of our greatest heavenly bodies, were taken by the old alchemists to represent what were then the rarest and most valuable metals, gold and silver.

Iron from its usefulness in making implements of warfare, was dedicated to Mars, the god of war, and the sign which is supposed to represent the spear and shield of Mars, ♂, was universally adopted. It also did duty for Tuesday—Die Martis.

Mercury, named after the god Mercury, or the "morning star," was represented by the annexed figure ☿, which is a rough representation of the "caduceus," or wand with two snakes twining round it, which that god is always represented as holding. It also stood for Wednesday—Die Mercurii.

Copper was dedicated to the goddess Venus, and is represented by the figure ♀, being intended for the looking-glass of that goddess, on account, no doubt, of its smooth and bright appearance when burnished and polished. Friday, or Die Veneris, has also the same symbol.

The figure that represented lead, ♄, was supposed to be an imitation of the scythe of Time, or Saturn, being dedicated to that planet. The name "Saccharum Saturnii" being even now frequently used to indicate sugar of lead. Also the derivation of Saturday—Die Saturnii.

So we see that all these seven metals were well-known to the ancients, by whom they were considered to be compounds of mercury and sulphur in different proportions. The signs for some of the less known metals are also met with.

The metals arsenic and antimony were represented by characters, the origin of which seems to be unknown; arsenic by two circles connected with a bar, antimony by a diamond-shaped figure, probably on account of the crystalline appearance of that metal.

Cobalt was hardly known at all to the ancients, although the fact of its having a sign shows that something was known of it. Probably, judging from the similarity of this and the sign for arsenic, it was considered to be a modification of that metal, the hieroglyphics being very similar but inverted.

In the earlier days, zinc was unknown to the ancients; although brass was manufactured so far back as the Old Testament, and was the chief metal used in making the spears, shields, and armour in the Trojan war, yet zinc was not known as a separate metal. The brass was made by smelting together a mixture of copper and calamine (a mineral containing zinc). The symbol that formerly belonged to brass, has now fallen to the lot of zinc, and is something similar to that of copper, but only half of the circle remains, showing that brass contained half copper; the rest of the sign represented calamine.

The foregoing symbols were, as before mentioned, the most universal of the alchemical signs, but independently of these the old writers adopted a series of their own. In some of these we find the initial letter of the element used to denote the name, in connection with a sign or figure, which served to denote the nature of the substance. Thus, some used a circle ○ to denote a metal, and placed the initial letter inside. I may here mention that gold only required a dot inside the circle ☉, and was then identical with the pre-mentioned figure of the sun.

Again, acids were represented by a square figure □, with the initial letter enclosed.

The alkalies were represented by a triangle, standing upon its base △, and by placing the initial inside, the name of the alkali was indicated. The same figure reversed, gave the alkaline earths, thus ▽

An alloy of two metals was represented by joining the two circles each containing the initial letter of a metal, thus forming a combination of their two respective signs. Compounds were represented by joining the two separate symbols of the component parts, as to ▽□ indicate an acid and a base.

When a liquid state was to be denoted, as mercury in its normal state, an up-stroke was attached to the left-hand side of the figure ׀◯ ; thus ׀⊙ for gold in a state of fusion, etc., but a down stroke upon the same side ׀◯ denoted a state of vapour, as mercury volatilized by heat. Spirituous substances were signified, when a diamond-shaped figure was used ◇, as for ether. The non-metallic elements were expressed by strokes, thus Oxygen —, Nitrogen /, Hydrogen ↄ, Carbon C, so it will be easy to understand that the acidulous radicals of the non-metallic elements were formed by combinations of the above, thus ∠ the symbols of nitrogen and oxygen united denoted nitrates, hence nitrate of a metal would be written ◯∠.

In a later date we find that sulphides, phosphides and carbides were known; these of course required no horizontal stroke, because they contain no oxygen and were written thus—⊙) sulphide of gold, the circle and dot to represent gold, the semicircular stroke, sulphur; ◯⌒ phosphide, ◯Ⅼ carbide. The symbols or signs for the oxides of the metals were written by attaching the symbol for oxygen — to the top of the circle thus ◯‾.

So it will be seen that if the foregoing signs were once committed to memory, it would be very easy to write the symbol for any inorganic substance, although the quantities and proportions of the elementary ingredients would remain unexpressed, and for that reason these signs would be quite useless at the present day, when no organic compound can be expressed without the proportions of the ingredients are clearly shown; but at that time few, if any, organic chemicals were known (that is the composition of them) so of course that system of shorthand hieroglyphics answered every purpose.

Again to return to an earlier date I may also mention that certain signs were used to express the different chemical processes, as for instance ≏ to sublime, ▽ to precipitate, ◯⌒ to distill, ≋ to fuse, —+— to ignite. The latter sign had reference to the crucibles which were always impressed with a cross, thus ✠; the name crucible is derived from the word crux, meaning a cross. The testing of metals in a crucible was said to be the crucial test, for, as it is known, none but the nobler metals, gold, silver and platinum, will stand intense heat without oxidizing, so the origin of the cross on some crucibles and of the name crucible is apparent. There can be no doubt that the employment of symbols and signs as an abbreviated way of denoting the composition of bodies was suggested by the difficulty experienced in many cases of finding names to express the constitution of chemical compounds, especially minerals. One of the first men who sought to unravel chemistry from the mysteries and mazes of alchemy was Libavius, and he more or less succeeded. He discovered the perchloride of tin, even now known as the "fuming liquor of Libavius." Later on we find the theory of phlogiston causing a powerful interest in chemistry; indeed it was on the ruins of this theory that Lavoisier, Priestley and Scheele raised modern chemistry.

As regards the symbols in use at the present day I think that we may safely consider Berzelius to have been the founder; he seems to have been the first to change from the ancient signs and figures of alchemy. The result is that chemical formulæ are now so identified with chemistry that the chemical student must have a thorough knowledge of the different symbolic expressions.

The symbols of Berzelius still hold good, although his system has been greatly modified. He was the first to to connect the formulæ for compounds by algebraical signs. Although the utility of these algebraic formulæ cannot be denied, they have been found very lengthy when the object is merely to express the composition of bodies, and one of the chief abbreviations of Berzelius was to indicate degrees of oxidation by dots over the symbols; he also often dispensed with the plus sign, by writing combined elements side by side, the sign being understood instead of expressed thus H_2O, Fe S, instead of H_2+O, Fe+S. He also expressed the vegetable and animal acids by the first letter of their name with a dash over it; thus $\overline{T}$, $\overline{A}$, $\overline{C}$, stand for tartaric, acetic, and citric acids. Liebig and Poggendorff in modern days have made various modifications of these symbols, and brought them more or less to their present state of perfection.

I have no doubt that many of these signs will be recognized as old familiar friends that have often been gazed at, on some one carboy or another, with wonder perhaps as to what their meanings were, or whether they had any meaning at all. I, for one, am sorry to see the old custom of decorating the carboys with these ancient signs so fast going out of date; for these carboys of coloured water seem to be an institution that no chemist can dispense with, or rather I should say, dispense without, and I think if we must have them, we should have them as they were, in all their pristine beauty and mysterious significance. In old works may be found signs far different to those I have explained, but these were not so generally used by alchemists.

Review.

MEDICINAL PLANTS, being Descriptions with Original Figures of the Principal Plants employed in Medicine, and an Account of their Properties and Uses. By ROBERT BENTLEY F.L.S., and HENRY TRIMEN, M.D., F.L.S. London: J. and A. CHURCHILL.

The general scope and character of this work have already been pointed out in the columns of this Journal, and we need therefore only allude to the progress that has been made in it during the past year. Sixteen parts have now been issued, containing altogether 117 plates. These include several drawings of plants not previously figured. Of these we may notice *Stillingia sylvatica, Dorema Aucheri, Toluifera Pereiræ* and *Ferula galbaniflua.* Some of the plates also are much superior to those which have appeared in other works.

The botanical nomenclature has been brought up to the latest date, many of the names adopted having been those advocated in the 'Pharmacographia.' A few, however, such as *Toluifera Pereiræ* for the balsam of Peru plant, *Artemisia pauciflora* for the santonica plant, *Schœnocaulon officinale* for the plant yielding cevadilla seed, will probably be new to most of our readers. The additional weight of authority given by the work under consideration may be expected to lead to their adoption in the next issue of the 'British Pharmacopœia.'

The botanical descriptions are very full and accurate, and the language employed is as free as possible from superfluity of technical terms, affording a striking contrast to the short, insufficient, semi-Latin descriptions so much in vogue at the present day.

Aided by the magnified details of the structure of the flowers, etc., on each plate, the reader, even if possessing only a slight knowledge of botanical terms, will be able, without any difficulty, to master the structure of such abnormal flowers as those of the aconite, hellebore, valerian, larkspur, violet, and castor oil plant, and to understand the details of very small flowers, such as those of the juniper, alder buckthorn, bistort or wormwood.

The colouring in the last few numbers has shown a decided improvement, that of *Rheum officinale* and some others being very true to nature. As a whole, however, it has scarcely come up to that standard of excellence which characterizes the work as a whole, and it will we trust receive more attention from the publishers than hitherto.

Considerable pains have evidently been taken to make the portions relating to materia medica as complete as possible, and the very latest sources of information have evidently been consulted. This is especially noticeable in the articles on aconite, santonica, coca, eucalyptus, galbanum and rhubarb, so that the work may be looked upon not only as an excellent descriptive work on medicinal plants but also as the most recent treatise on materia medica. This portion has also an additional value from the fact that the various roots, fruits, etc., used in medicine are in many instances represented of the natural colour on the plates, and in some instances transverse sections are given also so as to exhibit the internal structure. This is an improvement which we hope to see followed up. Possibly in a few cases a little more might have been said. Thus no mention is made under oil of thyme of its extensive adulteration, which may be deduced from the singular fact that it is usually sold at half the price it costs the wholesale dealer. The statement that yarrow owes its name of "nose-bleed" to its former high reputation as a vulnerary, scarcely coincides with the statement of Gerarde (on the page quoted by the authors in their bibliographical list) that "the leaues being put into the nose do cause it to bleed and ease the paine of the megrim." But these are minor matters. We trust that the work, which must entail great expenditure of time and trouble, will continue to give as much satisfaction as it has hitherto done. We are glad to notice that the plates have already been turned to an useful purpose in the economical museum at Kew, where they may be seen in glass frames illustrating the various products obtained from them. This example is worthy of adoption by science schools and museums, and nowhere could this example be more appropriately followed than in the museum of the Pharmaceutical Society. It is to be regretted that the plates cannot be obtained separately, only sufficient having been prepared to accompany the text.

BOOKS, PAMPHLETS, ETC., RECEIVED.

VIVISECTION. Being Short Comments on Certain Parts of the Evidence given before the Royal Commission. By GEORGE MACILWAIN, F.R.C.S. London: Hatchard. 1877. From the Author.

Obituary.

ALFRED SMEE, F.R.S.

We regret to record the death, on the 11th inst., of Mr. Alfred Smee, whose researches on electricity have lastingly associated his name with that science. Mr. Smee was elected a Fellow of the Royal Society in 1841, when only 23 years of age. For many years he held the appointment of consulting surgeon to the Bank of England. He was the author of several works on electricity, metallurgy, etc., and also of one entitled "My Garden," which was reviewed in these columns and was the outcome of a very favourite hobby. Mr. Smee died at the age of 58 years.

Notice has been received of the deaths of the following:—

On the 28th of November, 1876, Mr. Alfred Kent, Pharmaceutical Chemist, Iffley, Oxon. Age 67 years. Mr. Kent had been a Member of the Pharmaceutical Society since 1853.

On the 28th of December, 1876, Mr. Eldred Edward Tomlinson, Chemist and Druggist, Whitehaven. Age 20 years.

On the 7th of January, 1877, Mr. William Henry Wardle, Pharmaceutical Chemist, Stalybridge. Aged 58 years. Mr. Wardle had been a member of the Pharmaceutical Society since 1858.

On the 13th of January, 1877, Mr. Joseph Taplin, Pharmaceutical Chemist, Bristol. Aged 61 years. Mr. Taplin had been a Member of the Pharmaceutical Society since 1852.

We also learn from a paragraph in the *Western News* of the death of Mr. Thomas Clarke, of Bodmin, in his 90th year. Mr. Clarke for many years carried on the business of a Chemist and Druggist, and was one of the promoters of the Bodmin and Wavebridge Railway, which is said to have been the second railway opened in the United Kingdom.

Correspondence.

MILK OF SULPHUR.

Sir,—Although probably he does not mean it, Mr. H. Brown, L.R.C.P., etc., has surely "touched widely enough this subject" of milk of sulphur. From the context it may be gathered that he means "comprehensively" or "conclusively" when he uses the word "widely."

Although he seems to think that now he, the "Daniel come to judgment," has spoken, all must hereafter hold their peace, will you allow me to say that his arguments and quotations appear to me either "misty" or decidedly against his own view of the matter.

He quotes the old official London and Edinburgh formulæ for making the very medicine which the Runcorn authorities pronounce "a poisonous drug" and a preparation which "destroys more human lives than half a dozen plagues." Can he be serious in thinking that anyone at any time ever succeeded or even attempted to wash out the calcium sulphate with "parcels of water?" Has he ever tried to do it, or has he ever seen this pure "lac sulphur of bygone days?" Has he ever made or ever seen lac sulphur prepared according to the quoted Edinburgh formula free from calcium sulphate?

When we remember that, according to his own figures, it would take nearly a hogshead of water to clean a pound of the lac sulphur, we may indeed well admire "the diligence" of such "washings." What ground has he for asserting then that "no one will affirm that the lac sulphuris prepared in the Edinburgh form could by any possibility contain calcium sulphate?"

He does not say where "we are told if common sulphur," etc.; probably it was in the "Old Dispensatory" he before mentions; but I am at a loss to see how this quotation proves the absence of calcium sulphate in "lac sulphuris made in 1720."

I would call Mr. Brown's attention to Professor Redwood's evidence, page 585, as to the alteration between the 1721 and 1746 Pharmacopœias. Surely there was a reason for leaving out the alternative muriatic acid process and retaining only the formula which produced a mixture of the calcium sulphate? Might not some members of the "scientific committee" of 1746 have had similar experience to Mr. Pemberton, page 584?

With regard to the precipitated sulphur, Dr. Todd Thompson says, in 1833, "It differs in no respect from sublimed sulphur, and is an unnecessary refinement," etc. Probably his opinion caused it to be entirely omitted from the 1836 Pharmacopœia. But such a statement cannot be made with regard to milk of sulphur. It does essentially differ both from sublimed and precipitated sulphur. This the public have learnt from experience, and there has been a continued demand for the compound article, notwithstanding its complete omission from the 1836 Pharmacopœia.

Perhaps this demand was the reason for placing sulphur præcipitatum in the 1851 Pharmacopœia. But I would ask the question seriously, Did not the compilers of the 1851 edition make the same mistake as is being continually made now, in jumping to the conclusion without any experience that the calcium sulphate was not a beneficial mixture with the sulphur?

Mr. Brown also, without reference to any experience or researches of his own or any one else which warrant his speaking in such an *ex cathedrâ* manner, says, "I can see no advantage in continuing to make an article according to an old form," etc., but, with the greatest respect, I would ask why must the public receive his *ipse dixit*, or even the mere assertion of better known medical men, if they are not fortified by facts.

Perhaps it is through forgetfulness or lack of information on my part, but what Mr. Brown says about "selenited sulphur" and "selenited (*sic*) lac sulphuris" is a perfect mystery to me. My impression, however, is, that he has, as he says, "touched widely enough on this subject" too, and left it in a "misty cloud."

I can only now refer to the abridged edition of Pereira, but I find nothing there about these mysterious bodies, nor have I been able to find anything in either of the British Pharmacopœias about the composition of lac sulphuris, although Mr. Brown alludes to it.

In the absence of any facts proving that the mixture is injurious, and considering the great and continuous demand for the genuine old milk of sulphur, I think I have far greater warrant than Mr. Brown has for his concluding sentence, in saying that while, no doubt, B. P. formula should always be used for sulphur præcipitatum, calcium sulphate should always be an ingredient in milk of sulphur.

Surely chemists in business may reasonably protest against this continued interference of half instructed "analysts" in matters that they do not understand, and we may well express our surprise that the Runcorn magistrates preferred the opinions of Dr. Bell to those of such a veteran as Professor Redwood, sustained as he was by Mr. Pemberton.

Barnstaple, Jan. 13, 1877. W. SYMONS, F.C.S.

Sir,—All your correspondents seem to have overlooked the fact, that the last London Pharmacopœia of 1851 (by which chemists for seventeen years should have been guided) describes "Milk of Sulphur," thus—

"Sulphur Præcipitatum Milk of Sulphur." { Sulphur precipitated from sulphuret of calcium by hydrochloric acid.

Lee Bridge, Lewisham. EDWIN L. CROW.

[*** In the London Pharmacopœia, 1851, sulphur præcipitatum is included among the articles described under the head of materia medica. The description given of it (translated) is, "Sulphur precipitated from sulphuret of calcium by hydrochloric acid."

In Phillips's translation, which was edited by Denham Smith, the formula from the Pharmacopœia of 1824 is given, and there reference is made to lac sulphuris, of 1721, and sulphur præcipitatum of 1746—1788, and 1809, the several pharmacopœias in which it was ordered.

In the London Pharmacopœia of 1836, sulphur præcipitatum was omitted altogether.—ED. PH. J.]

AMENDMENTS TO THE PHARMACY ACT, 1868.

"Dig the well before you are thirsty."—CHINESE PROVERB.

Sir,—The members of the Society have doubtless read with much interest the debate at the last Council meeting upon Mr. Hampson's motion (to appoint a sub-committee to consider any desirable amendments to the Pharmacy Act, 1868), and I, for one, must express my thanks to that gentleman for refusing to acceed to Mr. Hills' request that the matter should be discussed in committee—*i.e.*, out of sight and hearing of the members of the Society and the trade which that Council is elected to represent.

Your readers must indeed have a very small appreciation of the humorous if they have not enjoyed a hearty laugh at the proceedings thus placed before them—for it is no ordinary spectacle to see two gentlemen (who during the debate have done their utmost to throw out the original motion) suddenly propose an amendment almost twin-brother to the motion against which they have been fighting; for if I am correctly informed that the Law and Parliamentary Committee consists of all the members of the Council, it can surely matter very little whether a sub-committee be chosen by the members sitting in Council or in Committee.

"Strange that such difference should be,
'Twixt Tweedledum and Tweedledee."

Your readers have doubtless turned with interest to the remarks of Mr. Sandford, the father of the Pharmacy Act, 1868, and they can scarcely be surprised that he considers that it would be difficult to improve it; but when he says that "he considers the appointment of such a committee as the proposed utterly needless," I must (notwithstanding the respect that all must feel for so eminent a pharmaceutist) beg leave to point out that those who live neither in the Paradise of Piccadilly nor the Eden of Oxford Street feel that the Act has imposed upon them examinations and restrictions, costing each one a considerable amount of money and labour, and in return has made assistants scarce and driven many of their best workers from the trade, and has failed to protect them from the competition of the unlicensed company or the unregistered dealer in drugs.

While we outside peris are not so unreasonable as to suppose that the Council could remove all our difficulties in a breath, it would not appear unwise to examine the Act with a view to amending (when possible) our position with regard to—

The unscrupulous shifts of unregistered drug vendors.

The competition of unlicensed companies.

Evasions of the poison regulations under cover of medicine stamps.

The application of fines and penalties to Her Majesty's Treasury instead of the treasury of the Pharmaceutical Society, etc., etc., etc.

It may be that no opportunity will arise for improving our position this session, but when a sub-committee has found out and considered carefully what the trade wants, we shall then be in a better position to ask for it when the opportunity presents itself.

Birmingham. WALTER J. CHURCHILL.

CHEMISTS AND DRUGGISTS AND THE MEDICAL ACTS.

Sir,—I am sorry that I have not been able to convince Mr. Yewdall that an apothecary is by the Act, 1815, and other more recent Acts, assumed to be a legally qualified practitioner of medicine. I cannot admit that the term "medicine" is synonymous with "pharmacy" any more than I can admit that a person who practises surgery is simply a surgical instrument maker. Besides, my friend contradicts himself, for he says "the only person qualified to treat sick people was the physician who was lawfully licensed to carry on the practice of physic." Now, if "medicine" mean "pharmacy" and "physic" mean "medicine," then the physician was, according to Mr. Yewdall's own showing, only allowed to practise "pharmacy," and therefore was no more qualified than the apothecary. The latter was required to pass an examination as to his knowledge and skill in the science and practice of medicine, and although there is no definition of the profession of an apothecary, except that given in 5th section, so far as the Act, 1815, is concerned, a general practitioner and apothecary are spoken of in the Medical Act as being one and the same; and in the Sale of Poisons Act, sect. 17, an exception is made in the case of any medicine supplied by a legally qualified apothecary to his patient.

One difference between a physician and an apothecary is this: the former is, by a bye-law of the college, forbidden to dispense medicines except for his own patients; the latter is not only allowed to practise medicine on his own account but is also bound by law to dispense the prescriptions of a legally qualified physician.

I would refer Mr. Yewdall rather to the wording of Baron Bramwell's decision than to the decision itself.

Finally, I wish it to be understood that I am giving no opinion on the advisability or otherwise of chemists prescribing, but simply regarding the subject in a legal point of view.

Batley Carr, Dewsbury. J. FRYER.

Sir,—As several of your correspondents seem at a loss to understand the true status of the apothecary, may I ask if you will indulge me, by inserting in your next week's issue of the Journal the subjoined portion of abstract of principal laws relative to medical men?

"The practice of an apothecary may now be said to consist in attending and advising patients afflicted with diseases requiring medical (as distinguished from surgical) treatment, and prescribing, compounding, and supplying medicines for their cure or relief. The class of cases which it is the province of the apothecary to treat includes most of the diseases by which the human frame is affected; for instance, diseases of the brain, the lungs, the heart, the stomach, the liver, and the bowels, when the disorder is unattended by any external wound, sore, or tumour, and when medical treatment, unaided by any manual operation, is called for. A penalty of £20 may be inflicted, for every such offence, upon any person acting or practising as an apothecary in England or Wales, without the licence of the Society, and a penalty of £5, for every such offence upon any person acting as assistant to an apothecary to compound and dispense medicines, without having obtained the certificate of the Society. The Society can, therefore, afford no protection against practice by bone-setters, and that class of persons, but it can supply an efficient safeguard against irregular practice by chemists and druggists, for it has been held that a chemist who not only sells but also applies and administers medicines, in the ordinary course of attending patients, practises as an apothecary, and is not exempt from the penalty."

After a careful perusal of the above, I think we may fairly conclude that the licence granted by the Society of Apothecaries of London is truly medical, and one that three-fourths of our British medical practitioners have selected, being quite equal to the medical licence granted by the Edinburgh College of Physicians. Also the wording of the licence of Apothecaries' Hall of London is that its recipient has been carefully and deliberately examined as to his skill and abilities in the science and practice of medicine; and further, that he is duly qualified to act as an apothecary.

ROBT. E. THREADGALE, L.S.A. LOND.

Upper Norwood.

Sir,—In reference to the Act of 1815, I must confess that before I read it carefully through, I thought that at that time the chemist and the apothecary was one and the same person, but after reading it I saw that I was in error.

If the chemist had been one with the apothecary, why should the chemist have been exempt from registrations under the Act and his trade or business so clearly defined? For in clause xxviii. it reads:—

"Provided always that nothing in this Act contained shall in any way affect the trade or business of a chemist and druggist in the buying, preparing, compounding, dispensing and vending drugs, medicines and medicinable compounds, wholesale and retail," etc.

There is not any reference to his right to practise medicine.

We need not go so far back as 1815 to know that the practice of medicine by a chemist and druggist is contrary to law. Let us see what the Pharmacy Act of 1868 says on the subject.

It opens thus,—"Whereas it is expedient for the safety of the public, that persons keeping open shop for the retailing, dispensing and compounding of poisons and persons know as chemists and druggists, should possess a competent practical knowledge of their business," etc.

This clause shows what a chemist and druggist may do, and clause xvi. states what he may not do. The latter portions of it run thus:—

"Provided always that registration under this Act shall not entitle any person so registered to practise medicine or surgery, or any branch of medicine or surgery."

Having found out how we stand from a legal point of view, the question arises, What are we to do? Well, I see only one way open to us, that is to petition Parliament to exempt us from all fines and liabilities whatever, by reason of our advising and prescribing over the counter, for any ailment that may come under our notice, providing that we be not allowed to visit any person at his own home, nor to sue in a court of law for advice or visits. Surely this would satisfy the medical profession.

W. B.

Horncastle.

THE HYGIENIC INFLUENCES OF THE PINE AND EUCALYPTUS.

Sir,—Dr. Bond's second letter calls for but little reply from me. It is chiefly concerned with personalities which I cannot discuss and with statements which, if they prove anything, establish the fact that their author is unacquainted with modern chemical research. I requested Dr. Bond to kindly point out to me where I could find his published researches, and he refers me to an advertisement column!

One more word in regard to terebene. The substance ordinarily known by this name was not discovered by Dr. Bond, while in relation to its uses as a disinfectant or antiseptic, I adhere firmly to my already stated opinions. Dr. Bond should be precise in his discussions; Sanitas, which is my discovery, is not a solution of camphoric acid, as he states, but a mixed solution of peroxide of hydrogen, camphoric acid, camphor, etc. I hope shortly to provide Dr. Bond with a better opportunity of defending the virtues he claims for terebene, meanwhile I must decline to continue this correspondence.

CHARLES T. KINGZETT.

LARGE DOSE OF VIN. ANTIM. TART.

Sir,—When I have seen cases published of poisoning by tartar emetic, I have often thought of a case which left a serious impression on my mind, although it happened many years ago, as it bears the caution, that the materia of the pharmacist are like edge tools, and to use them for practical joking is as criminal as presenting a pistol at a man. Perhaps it may be worth relating.

About ten years before Jacob Bell founded the Pharmaceutical Society, I was in business as a chemist in Brazil; my servant (an African slave, I could get no other servant) annoyed me by drinking my wine, a very cheap Spanish wine, which in the hurry of business I often forgot to lock up.

I filled a bottle with vin. antim. tart., and soon found the man had fallen into the trap. I found twelve ounces gone, which at two grains to the ounce contained twenty-four grains tartar emetic. I was soon alarmed to find that he was not only purged and vomiting, but that he had convulsions or involuntary twitchings of the arms and legs, as he lay on his bed.

I lost no time in looking for an antidote, and soon prepared a quart of decoct. cinchonæ from the best red bark. I gave this in half-pint doses, and the convulsions were relieved; but I had to prepare another quart, which the black drank freely, and after a long sleep he recovered, for which I was very thankful. I received a serious lesson, which I would not repeat for any consideration; but I am now an old man.

JOSEPH LEAY.

S. A. Purvis.—*Nessler Reagent.*—Boil 35 grams of iodide of potassium and 13 grams of corrosive sublimate in 800 c.c. of water, stirring until dissolved. Add cold saturated solution of corrosive sublimate, cautiously, until the precipitate of red iodide of mercury remains permanent. Then render alkaline by adding 160 grams of solid caustic potash, or 120 grams of caustic soda, and dilute with water to a litre. Finally, add more solution of corrosive sublimate and leave the mixture to settle (Wanklyn).

"*Novircus.*"—Apply to the Secretary for a copy of the Regulations of the Board of Examiners.

"*Derfla.*"—We cannot say.

A. P. S. (Edinburgh).—Your question should be addressed to Professor Attfield.

"*Inquirer.*"—(1) Several recipes for this preparation have already been given; see vol. vi., p. 598. (2) The Mistura Alba, of the King's College Hospital Pharmacopœia, is:—

Magnes. Carb.	10 gr.
Magnes. Sulph.	60 „
Aq. Menth. Pip.	1 oz. Mix.

It is also in several hospital Pharmacopœias varying in strength.

G. Dobson.—(1) Roscoe's Lessons in Elementary Chemistry, published by Macmillan; (2) We are not acquainted with such a work.

G. W.—The examination extends only to an elementary knowledge in the subject.

W. T. H.—We think the advantage would lie in the other direction.

H. Cock.—The office of the *Lancet* is No. 423, Strand.

R. Williams.—The phylloxera is an insect which has done serious injury to the vines in several wine districts. See vol. v., p. 405.

"*Minor.*"—The sole object of the examination is to test whether the candidates are sufficiently skilled and competent to conduct the business of a chemist and druggist. When this has been done we do not think that more can be "demanded."

"*Alpha.*"—Ure says that strong nitrous acid diluted with five volumes of water and a little sal ammoniac added, is used.

"*Compound Radical.*"—It is not necessary to pass any examination before using the title.

W. Lea.—The colour would vary according to the age, purity and freedom from oxidation of the phosphate of iron, but, we do not think without filtering, which is not intended should be done, the mixture can be of a straw colour. There is nothing to produce sweetness in the mixture, so that there should not be any difference in this respect between your mixture and that of the London house.

"*Kino.*"—The substance is asbestos.

COMMUNICATIONS, LETTERS, ETC., have been received from Mr. Abraham, Mr. Taplin, Mr. Haydon, Scotus, Dispenser, Assistant, W. L. A.

"THE MONTH."

Under this title we propose to refer cursorily once a month to subjects which may appear to present points of more or less passing interest to the readers of this Journal. For instance, it has more than once been suggested that a short notice each month of the medicinal plants which happen to be in blossom would be acceptable. Besides dealing, therefore, with topics allied to science generally, it will be the object of this and subsequent papers to provide such a list as will enable a botanical student to see, at the proper time and place, all the plants of medicinal interest in the botanical gardens around London, or which may be found in a wild state in this country.

A country ramble at this time of the year will yield but very few specimens in flower of any kind, and none at all of a medicinal nature. The white dead-nettle, shepherd's purse, dandelion, daisy, and in the southern counties the fragrant winter heliotrope (*Petasites fragrans*), with possibly a stray snowdrop or primrose here and there, and the catkins of the hazel, are probably all that will reward the collector. Nor must a long list be expected even from botanical gardens or hothouses at this time of the year.

At Kew, the herbaceous ground shows very little of interest. One specimen is, however, worthy of special notice, since it can be seen to the best advantage at this time of the year, when all the leaves have fallen off. This is the Turkey rhubarb plant (*Rheum officinale*, Baill.), which, introduced only a few years ago by the late Daniel Hanbury, has now grown to a large size. It may be found by the side of the walk through the herbaceous ground near the No. 2 Museum. The portion visible above ground is a sort of crown (*sympodium*), consisting of several stumps, or short thick shoots, about 8—10 inches high, and 4—5 inches in diameter, covered with the scars of fallen leaves, and presenting here and there small leaf-buds in the axils of the scars. It is from this portion of the plant that the Turkey rhubarb of commerce (according to Professor Baillon) is prepared, the subterranean portion not affording pieces of equal size. With this statement the large specimens of rhubarb in the Museum of the Pharmaceutical Society appear to correspond, as they closely resemble the shoots in shape and size. It must be remembered, however, that some Russian rhubarb is also derived from another species, *Rheum palmatum*, var. *Tanguticum*, Max.

In the economic house at Kew several medicinal plants may be seen in flower. Almost the first to attract notice is the star anise, *Illicium anisatum*, L. In China and Japan it grows to the height of a small tree, but as growing at Kew it much resembles in size and habit the sweet-scented daphne (*D. Cneorum*), being about 2 feet high, and having smooth entire lanceolate leaves somewhat crowded together towards the ends of the branches. The pale yellowish-white sessile flowers may be seen here and there, nestling among the upper leaves or growing out of the naked stem near the scars of fallen leaves. The flowers are about the size of the common daisy, or perhaps a little larger, and have a faint odour not at all resembling that of aniseed. The bracts, sepals and petals are all of the same yellowish white colour, so that at first sight it seems scarcely possible to distinguish where the one begins or the other ends. More careful observation, however, will show that the sepals are broader and less tapering than the petals, while the bracts are much shorter and at the back are tipped with reddish-purple. The stamens, which are numerous, having very short filaments, are closely packed in the centre of the flower, and hence resemble the yellow disk of a daisy in appearance. After a time the sepals, petals and stamens fall off, while the bracts remain for some time longer. The carpels may then be seen to be quite erect on the thalamus, not spread out as they afterwards become in the well-known star anise fruit.

The variety planted in the neighbourhood of temples in Japan is sometimes described as a distinct species, under the name of *I. religiosum*. It is used in Japan to decorate the tombs, and the bark is burnt as incense. Singularly enough the leaves both of this species and of that which grows in Florida have the repute of being poisonous.

The *Drimys Winteri*, Forster, has a sufficient general resemblance to the last plant to indicate, even to a casual observer, that it belongs to the same natural order. As growing at Kew, the plant is from two to three feet high, and the stems are longer and more distantly branched than in the *Illicium anisatum*; but the leaves are similar in character, if anything rather longer, and with the white midrib contrasting rather more strongly with the dark green colour of the leaf. The flowers are also similar in colour and appearance, but are arranged in small terminal umbellate cymes, each branch of which consists of a group of from three to five flowers. When in fruit it differs still more from the star anise plant, the carpels being berry-like and containing several seeds. The specimen at Regent's Park Botanical Gardens is of more vigorous growth, but is not at present in flower.

In South America *Drimys Winteri* is a tree, but appears to vary very much in its botanical characters in different districts. It may be here remarked that the Winter's bark of commerce is not derived from this tree, as it should be, but from *Cinnamodendron corticosum*. True Winter's bark is of a red brown colour and has a very rough inner surface.

Boldo (*Peumus Boldus*, Mol.) will be remembered as a plant which was brought into notice in this country a few years ago as a remedy for certain liver diseases, and a tolerably full account of it was given in the pages of this Journal.* It may now be seen in blossom at Kew, and also at Regent's Park. The specimen at Kew is but a small one, but that at Regent's Park more nearly approaches its size in its native country, Chili, being between 12 and 18 feet high. It is an evergreen shrub, having much the aspect of the holly oak, *Quercus ilex*, L. The leaves, which are opposite, are remarkably convex, probably owing to the fact that the epidermis of the under surface of the leaf has only one layer of cells, while that of the upper has two or in some parts three layers; they are oval in outline, from 1 to 2 inches long and ½ to 1 inch broad, rather rigid and very rough to the touch. This roughness is due to little prominences, bearing stellate hairs, scattered over the surface of the leaf. The flowers, which have a delicate verbena-like odour, are rather small, being about the size of those of the lime tree, *Tilia Europæa*, L., but with much shorter stamens; they occur in small clusters (corymbose cymes) at the end of the main

* *Pharm. Journ.* [3], vol. v., p. 405.

branches or of short lateral branches. They are of a pale yellowish-white colour, contrasting well with the dark green foliage. Both the plant at Kew and that at Regent's Park bear only staminate flowers. The sepals (5) and petals (7) are very similar in appearance; the sepals may, however, be distinguished by being much more hairy externally than the petals, as well as shorter and rather broader. The stamens, which are numerous, are shorter than the petals upon which they are ultimately bent back. The filaments have two curious glandular appendages near the base, very like those to be found on the stamens of the bay tree. The anthers of the Boldo tree do not, however, open by valves as in the bay tree, but by longitudinal slits. The fruit, consisting of small drupes about the size of haws, are eaten in Chili. The bark is used for tanning, and the wood for making charcoal.

The *Helleborus niger* is now in blossom at the Botanical Gardens, at Regent's Park, and may be seen in bunches in Covent Garden market, where it is well known under the name of the Christmas rose, a name which it derives partly from its resemblance to a wild rose, and partly from its commencing to blossom about Christmas time. It may not uncommonly be seen also in country gardens. It is readily distinguished from all the other species of the genus by its bracts not being leaf-like; all the other species in cultivation or found wild in England having leafy palmate bracts, or flowers terminal on a leafy stem. The flower stalk arises directly from the ground (scape), and bears usually one, but sometimes two, blossoms, which have one or two concave bracts beneath them. The calyx is white, and consists of five distinct sepals. The petals are small, green and tubular, and form a whorl, which is almost hidden by the stamens. The base of the petals tapers into a short stalk, and inside the bottom of the petal will be found some honey-like fluid secreted by the nectariferous base of the tube. Projecting beyond the stamens are the styles of the apocarpous ovary—the carpels of which are many-seeded, and ripen in the form of follicles. Similar petals to those of the Christmas rose may also be seen in the winter aconite, *Eranthus hyemalis*. The sepals, unlike those of most of the Ranunculaceæ, are persistent.

Daphne Mezereum.—At Regent's Park this little shrub is just beginning to blossom in the open air. The flowers, of a pale purplish-red tint, are arranged in small clusters of about three in number along the upper branches. They are quite sessile, and are surrounded by several scaly bracts. The calyx, for there is no corolla, is four-parted, and has eight anthers, arranged in two rows, sessile in the tube of the calyx. When the flower is fully grown, the tube of the calyx separates into two layers, which are readily seen on slitting open the flower. The ovary is superior, one-celled, with a short style and button-shaped stigma. The ovary when ripe forms a scarlet drupe. All the plants of this genus are remarkable for the toughness of their bark and for their acrid properties. The Mezereum may be seen frequently in cottage gardens, and rarely in woods—in which, in most instances, it is probably an escape.

The following plants possessing an indirect interest for the pharmaceutist are also in blossom at Kew:—*Osmanthus fragrans*, an oleaceous shrub, the small flowers of which are used by the Chinese for flavouring tea, and which possess a powerful fragrance exactly resembling the odour of Gosnell's violet powder *Kola acuminata*, a sterculiaceous plant growing in tropical West Africa, where the seeds are used, under the name of Cola nuts, as an aid to digestion, and which are remarkable for containing theine; also several varieties of the tobacco plant. The varied forms of the fruits of *Capsicum annuum* are also well worthy of observation, both at Kew and at Regent's Park.

In other scientific directions there is but little specially worthy of record; this month, the first of the year, being one which is rarely fruitful of results so far as their publication is concerned. The reason of this is, that the various learned societies have but just commenced their after Christmas sessions, and have scarcely got into activity again. This season, however, abounds in lectures of various kinds and of various merits, of which those delivered at the Royal Institution attract not a little attention from the outside public. The work of this Institution takes the character of interpretation to the unscientific public of scientific advances, and no doubt serves a very useful purpose in its way; the danger to be anticipated from its influence is not slight, however, for the public, knowing no better, regard it as the seventh heaven of science, and its professors as the archangels thereof.

Scientific men must have been disappointed with the discourse given by Professor Tyndall on the evening of Friday, the 19th inst. The title chosen by Professor Tyndal was "A combat with an infective atmosphere," and suggested something more striking than was forthcoming. Virtually, the discourse constituted a *résumé* of various researches, including those of Professor Tyndall, in reference to the so-called germ theory, and the question of spontaneous generation of life. The lecturer recalled to the memory of his audience the fact which he had demonstrated on a previous occasion, that a ray of light is visible only by means of the vibrating motes which float about in it, and that if time be allowed, these motes settle perfectly, so that a ray of light passing through the atmosphere which previously swarmed with them is no longer visible. It is to these motes seen in the sunbeam that Professor Tyndall attributes the power to start putrefactive and other processes of life in certain infusions from vegetable and animal sources, and indeed this is what he claims to have established. But before noticing further his experimental observation we may point out that he was anticipated to some extent by a writer of twenty or thirty years ago. L. H. Grindon in his work entitled 'Life, its Nature' (2nd edition 1857), writes—"It is not improbable that the glittering *motes* seen in the sunbeam when it shines through a small aperture into a dark room, consist in part of these otherwise imperceptible *eggs* and *seeds*. Light we know is the great and universal revelator." We pass on from this interesting historical note, to follow Professor Tyndall somewhat into his methods of experiments and arguments, and these may be very briefly described. He has taken infusions of various kinds, and exposed them to an atmosphere which is rendered free from these so-called life motes by various means, such as simple deposition, expulsion by steam, or exhaustion with an air pump, and he claims to have established in this way that such an atmosphere has no power to cause fermentation or putrefaction in any vegetable or animal infusions.

In spite, however, of all this, Dr. Bastian claims to have proved the doctrine of spontaneous generation of life, and as the matter is still in dispute and is not a one-sided question, we are not disposed to attempt any settlement of it on paper. We cannot, however, depart from this subject without calling attention to the defective methods of experiment employed by Professor Tyndall. He confessed that for a long time his results had been directly opposed to his own theory, but impressed with the truth of this latter he investigated and investigated until the matter cleared up. In short he ultimately found he had been introducing air containing life-germs into his solutions while charging his tubes with the various infusions. He was in the habit of charging these tubes by pouring the liquids through a tube plugged with cotton wool, and, as every chemist knows, it is almost impossible by this method to ensure that no air shall pass down the tube with the liquid. Finally, however, having made this discovery, he henceforth employed, what a chemist would probably have used in the first place, a separating funnel, by which it is possible to introduce into a vessel to which it is attached the liquid contained in it without permitting any ingress of air.

Professor Gladstone's lectures on the chemistry of fire are now concluded; among other matters he dwelt somewhat upon the spontaneous combustion of various substances, as hay, cotton waste, small coal, pyrites, etc., and finally discoursed on the means and methods of extinguishing fires.

On Thursday, the 19th inst., Dr. C. R. A. Wright delivered at the same Institution, the first of his course of lectures on "Metals, and the chief industrial uses of these bodies and their derivations." After some introductory matters, and general considerations regarding the constitution of metallic bodies and their sources in nature, he proceeded to describe the various processes of volatilization, amalgamation, smelting, liquation, etc., for metal extractions. In conclusion, he treated of native metals and refining processes, and the means of isolating metals from simple ores.

The pharmaceutical world has of late been disturbed by discussions on the milk of sulphur question, but as this matter has been treated of somewhat fully in these columns, we shall here only point out what is in our opinion a salient feature. The various prosecutions have been undertaken upon the basis of the Food and Drugs Act, but it is questionable whether milk of sulphur can be regarded as a drug, and if it is not a drug in a legal sense, the prosecutions are, from that point of view, unjustifiable. At least this is the view which is taken by many pharmacists, who will still continue to sell "milk of sulphur" when asked for it, but who will supply "precipitated sulphur" if the request takes that form.

Of late there have been several outbreaks of typhoid fever, notably at Salford, and attempts have been made as usual to connect the outbreaks of the disease with the bad nature of the milk supplied in these districts. Thus at Salford, it is stated that all the sufferers from typhoid fever have been supplied with milk from the same dairy. Notwithstanding this, however, it is extremely desirable to investigate the matter more fully, for apart from a sort of logical process of exclusion there is no scientific evidence bearing out this assumed relation of the disease to the impure nature of the milk consumed.

Much attention has of late been directed to the economic production of gas suitable for use as a fuel. It is said that by the Lowe process it can be made at a cost not exceeding 8*d*. per 1000 cubic feet, a figure which would allow of a very wide and cheap consumption. It is made, as is well known, by the mutual decomposition of petroleum vapour and steam by means of coke at a high temperature, and therefore consists in the main of carbonic oxide and hydrogen gases, into which all solid fuel may be converted by means of heat before it is burnt, as for instance in the gas furnaces introduced by Mr. Siemens. It seems, however, very questionable whether gaseous fuel prepared from petroleum—a material so much more costly than coal—can possibly be cheaper to use as fuel.

While speaking of this matter, it is worthy of remark, that a method of using petroleum as the fuel for steam engines has been invented in Italy, and patented in America and elsewhere. The medium employed is asbestos, which being inconsumable and a non-conductor is said to allow of the safe combustion of petroleum, while by its use there is saved a large percentage of heat, which would otherwise be lost. For many purposes the asbestos is made into a pliable millboard of one-eighth of an inch in thickness and with this material the furnace may be coated both externally and internally.

Mr. Churchill, the British Consul at Resht, Persia, has recently made a report about the naphtha wells in the Caucasus. These wells are situated near the town of Bakou, and for centuries naphtha has been extracted from them. In 1874, the production, as calculated by the tax inflicted by the Government, amounted to 1,120,000 poods of petroleum and no less than 180 works were in operation in the outskirts of Bakou. If an economy could be effected in the means of transport of the raw material to the manufactories, it is thought that the trade could fairly compete with that of America. As it is, the naphtha is said to be largely used instead of coal for steamers in the Caspian Sea.

Considerable attention has been given of late to nickeliferous pyrites which occurs plentifully in Italy. In some specimens there is contained as much as three per cent. of nickel, and if this nickel could be economically extracted it would probably find a ready market in Germany for use in the coinage departments. Since copper and silver are now so profitably extracted from pyrites, it is not unreasonable to expect that nickel may be as cheaply extracted from other ores in the future. Moreover, quite lately it is reported that a large mass of native iron has been found in Brazil (province of Santa-Catharina) containing as much as 36 per cent. nickel and 64 per cent. iron. These percentages correspond tolerably well to the formula Fe_2Ni.

The uses of salicylic acid and certain compounds chemically allied with it, have again during the past month attracted the attention of medical men. Thus at a recent meeting of the Clinical Society several papers were read treating of the use of salicin, salicylic acid and salicylates in rheumatic and other fevers, and the opinion was almost unanimous that these substances are capable of exerting beneficial influences almost peculiar to them. When such men as Dr. Weber and Sir William Jenner endorse such views, we may feel tolerably sure that they are reliable; at the same time it must not be forgotten that the last outcry about salicylic acid was in its disfavour. It was said to cause processes of irritation, and when applied to sore surfaces to produce certain forms of eruption. While the whole subject deserves serious investigation, we do not see that the action attributed to these bodies is at all peculiar, and this on chemical grounds. Salicylic acid is a benzene derivative ($C_7H_6O_3$), while salicin, although a benzene derivative, is one that is far removed from salicylic acid. So far as we know salicin is a sort of glucoside which splits up by the agency of acids into saligenin ($C_7H_8O_2$) and glucose ($C_6H_{12}O_6$). There are a number of facts of this character which would appear at first blush to indicate that the therapeutical value of the various substances above referred to is one that may prove common to nearly all benzene derivatives of a certain order. Thus carbolic acid comes naturally within the category (C_6H_6O), and camphoric acid also ($C_{10}H_{16}O_4$), while the relation in which these various substances stand to each other and the whole number to benzene is evident from the following formulæ :—

Benzene	C_6H_6
Carbolic acid (Phenol)	C_6H_5HO
Salicylic acid	$C_6H_4(COOH)(OH)$
Camphoric acid $(CH_3)(C_3H_7)$	$C_6H_6O_4$.

This formula for camphoric acid is written in this way for the sake of simplicity and to bring out the fact that it is an acid derived by the oxidation of methyl-propyl-benzene.

To return to our original observations, it will be remembered that when salicylic acid was first brought before the public notice, it was stated that the salicylates were valueless for the purposes assigned to the free acid, and hence its internal application was looked upon as a useless proceeding, for it inevitably results in the neutralization of the free acid by the sodic carbonate present in the blood. Now, however, much praise is given to these same salicylates for purposes identical with those to which salicylic acid is applied.

There have been several cases of prosecution conducted under the Adulteration Act, which are of interest, especially those referring to the presence of copper in "tinned peas." Chemically, it is easy enough to prove or disprove the presence and even amount of copper in such articles of food if proper care be taken. One of the precautions to be observed consists in causing any carbon to be entirely burnt off, otherwise acids will not thoroughly extract the copper from the mass. Assuming that the copper be obtained in the metallic state, a check over its amount is readily got by simple ignition in air of the platinum vessel upon which it is deposited, so that in this way a second weighing is obtained (of the oxide), which should correspond proportionately to the weight of metal found.

In the cases to which we have alluded, the magistrate was puzzled, not by the chemical question but by the medical opinions. Copper is undoubtedly a cumulative poison, as is testified by the amount invariably to be found in the brains, livers and spleens of persons after death, and it has been established fairly well that the metal exists in actual combination with the organic principles. But there is no medical evidence to show to what extent the presence of this copper is either useful or injurious. And it appears to us that the question to be determined by the magistrate in such cases, is rather whether the peas have been coloured by a cupric salt, or whether copper has been introduced by the method of preparation or perhaps from the tins in which the peas are packed. This the chemical evidence did not show.

G. Belluci* has continued some observations made originally by Lender, Gorup-Besanez, Morin, Monte, and others, regarding the production of ozone by the pulverization of water. The author has conducted his experiments in the neighbourhood of the falls of Terni, and beyond noticing the odour of ozone, he has observed that papers soaked in iodide of potassium and starch turn blue in contact with the atmosphere, even at a distance of 80—100 metres from the stream. On the same theory, the asserted presence of ozone in the air over ocean districts has been explained. Belluci concludes that the ozone is produced by means of the action of induced electricity upon the oxygen in the air, the electricity in its turn being derived from the friction of the water drops one against the other.

J. de Girard† states that the spontaneous alteration of anhydrous hydrocyanic acid is to be explained as arising from the calcium chloride used in drying the acid. The use of neutral calcic chloride furnishes a pure acid, but an alkaline chloride by reason of the excess of lime forms calcium cyanide, which with the water (contained in the hydrocyanic acid) gives rise to calcium formate and free ammonia, and it is known that even traces of ammonia are powerful to induce the decomposition of anhydrous hydrocyanic acid.

Yet another substitute for litmus has been added to the already lengthy list.‡ G. Pellagri finds that phyllocyanin, the blue colouring matter of flowers, is extremely sensitive to minute traces of free alkali. The phyllocyanin can be readily obtained from the iris, the violet, or the purple verbena, etc., by extracting the petals with warm water. The solution thus obtained is treated with dilute sulphuric acid until it is of a purple colour, and in this state it is sensible to the ammonia contained in rain water, or to the plumbic hydrate present in water which has been in contact with leaden pipes. These reagents turn it blue; a solution of potassium hydrate containing one part in 1,200,000 parts of water gives also with the solution of phyllocyanin a definite blue colour, while a solution of potash six times this strength turns it green.

COMPARATIVE EXAMINATION OF THE MORE IMPORTANT COMMERCIAL VARIETIES OF GALBANUM AND AMMONIACUM GUMS.§

II. AMMONIACUM.

BY EDWARD HIRSCHSOHN.

(*Continued from page* 572.)

1. *Historical.*—As is the case with galbanum little is known with certainty of the history of this drug. Thus, Martiny states that the first mention of ammoniacum was made by Hippocrates,‖ whilst

* *Gazetta Chimica Italiana*, vi., 88–97.
† *Compt. Rend.*, lxxxiii., 344.
‡ *Gazetta Chimica Italiana*, vi., 35–38.
§ From a memoir for which the gold "Suworow" medal has been awarded by the Medical Faculty of the University of Dorpat. (*Pharmaceutische Zeitschri für Russland*, April 15, 1875, p. 225.)
‖ 'Opera, ed. Foes,' p. 670.

Borszczow and Hanbury,* attribute it to Dioscorides.†

Discorides and Pliny both mention two sorts of ammoniacum; the best kind, called θραῦσμα, resembling olibanum, and having a smell like castoreum and a bitter taste, which was used for incense (the *ammoniacum thymiama* of Paulus Æginus); and the inferior quality, called φύραμα, having a resinous appearance, and mixed with stones and earth.

According to Pliny, the word ammoniacum comes from ἄμμος, sand, the mother-plant growing in a sandy soil. It is also stated that the word was sometimes written "armeniacum," indicating that the plant was a native of Armenia.

The time when Persian ammoniacum first came into use cannot be exactly fixed. It is not mentioned by the Greeks or Romans, probably, therefore, only the African was known to them. Avicenna (lib. ii. c. 8) does not give the source of this ammoniacum (called in the Arabic *assach*). The ammoniacum of Abu Mansur Mowajik (*Lib. Fund. Pharm.*, i., 35, ed. 1800) a Persian physician of the eleventh century, was without doubt the Persian sort, as was also the ammoniacum (*derukht ushuk*) of Beva Ben Khuas Khan (Ainslie 'Mat. Indic.' i. 160), who lived in the beginning of the sixteenth century. The Arabian words *assach*, *eschack*, and *ushuk*, applied by the last-named three writers to ammoniacum, resemble in sound *oshac*, by which it is at present known in Persia, and it may be assumed that all these names are synonymous. In Buchara the gum resin bears the name, *Kandal*. According to Bunge and Bienert the same name, and *Kämak*, are given to the plant in Persia; whilst Wright gives *weschak*, and Dr. Buhse *oschak* as the true names of the plant in that country. According to Borszczow, *Dorema Ammoniacum* is called by the Kirghises, *bal-kurai*, or "honey-cane." The Arabic name of African ammoniacum is *fasogh* or *fashook*.

2. *Origin*.—Dioscorides believed that ammoniacum was obtained from a species of *Ferula*, called *agasyllis*, which grew at Cyrene, in Africa; Pliny, on the contrary, called the plant *metopion*, and stated that it grew in Africa, in the neighbourhood of the temple of Jupiter-Ammon. The most celebrated botanists of the Middle Ages, C. Bauhinus, J. Bauhinus, Lobelius, and Dodonœus, quoted by Borszczow, say nothing new respecting it, but repeat with slight variations the statement of Dioscorides. Chardin,‡ who lived in Persia from 1666 to 1677, stated that the plant called *ouchag* by the Persians was met with plentifully on the southern borders of Parthia, i.e., south of Ispahan.

Chaw‖ and Jackson§ speak of the mother-plant of ammoniacum which they found in the Libyan Cyrenaica, and the latter compares it with a kind of fennel, called by the Arabs *feshook*. This plant according to him grows principally on the plains of the interior, but especially around El Araiche and M'Sharrah Rumellah.

From seeds found in the gum Willdenow¶ obtained plants which he named *Heracleum gummiferum*, but which Sprengel identified with *Heracleum Cyrenaicum*; this species, however, according to him, contains no juice resembling ammoniacum.

More exact information as to the origin of this gum resin is given by Johnson, Hart, and Wright. Johnson* saw a large quantity of the ammoniacum plant in the neighbourhood of Jesdekhast, in stony plains, which were quite covered with it. Hart† met with it in Bombay, in the neighbourhood of Yorda, Kaust, and Kumischa, in the Vauk district. He adds that it is there called Oschak, and contains ammoniacum in such quantity that the gum resin exudes from the smallest incision and even from the leaves.

In 1829 Don‡ described as a *Dorema*, one of the plants collected by Lieutenant Wright in the Persian province of Iran Adschemi and presented by him to the Linnean Society. But according to Merat,§ this plant was previously known to R. Brown, and still earlier to Fontanis, who found it while exploring the Levant on behalf of the French government, and gave some specimens and a drawing to the Museum of Natural History. But neither Brown nor Fontanis published anything on the subject, and the plants collected by them might have belonged to another species; so that Don must be considered the first to give a good description of the ammoniacum plant, the *Dorema Ammoniacum*, which appears to have a wide distribution in Persia. According to Borszczow the *Dorema paniculatum* discovered by Karelin and Kirilow in Songarei is identical with *D. Ammoniacum*; the same may be said of *Disserneston gummiferon*, Jaub. and Spach., and *Dorema aureum*, Stocks.

Between 1825 and 1832 Aucher-Eloy and Szowitz found in Persia two more indigenous species, *Dorema glabrum*, Fisch., and *Dorema Aucheri*.

Dr. Loftus also discovered other umbelliferæ in Southern Persia, such as *Dorema robustum*, *D. hirsutum*, and *D. odoriferum*. But these species of *Dorema*, according to Borszczow, cannot, on account of their rarity, be considered the origin of commercial ammoniacum. The most important, as before stated, is *D. Ammoniacum*.

According to Borzsczow‖ the entire distribution of the *Dorema Ammoniacum* has the shape of an obtuse-angled triangle, the south-eastern (obtuse) angle lies about 80° lat., and 33½° long., and of the two acute angles, the northern about 45° 30′ lat. and 84° long., and the western about 37° lat. and 73° long.

The same botanist describes the plant as follows:—"The plant seldom attains the height of 6 to 7 feet, or falls below 3 feet. The hollow leafless striated stem is furnished with pericladia at the internodes; as a rule it is very straight, and gradually tapers towards the top. At the base it is from 1 to 2 inches thick and towards the tapering end it gives off from 12 to 16 erect branches, upon which short-stalked simple umbels are arranged in a racemose manner, and from the flowers being nearly sessile have the appearance of capitula; the flowers are surrounded by a dense soft down. The fruit is ovate, in the unripe condition covered with hairs, but afterwards nearly smooth. The mericarps are flat, the dorsal surface having three narrow and two broad raised

ridges, extending to the margin; the furrows have each a single vitta, which rests upon the ridges, the commissure is flat, with two very broad vittæ. Before the flowering the stem is of a yellow-green colour and covered with a peculiar white down; after the flowering and during the formation of the fruit this down gradually disappears, and in specimens with ripe fruit the stem is nearly smooth and somewhat shiny. The stem leaves are entirely wanting, being replaced by the pericladia, the upper greatly prolonged portion of which is always reflexed. The size of the root-leaves varies between a foot and a foot and a half broad and long. The petiole is channelled at its base, but towards the top becomes nearly cylindrical. About 9 inches from the point of attachment it divides into three branches, which are once or twice pinnate. The leathery leaflets are arranged in pairs, except the terminal one, and are of an oval shape; in breadth and length they vary very much.

3. *Collection.*—Jaenson (1804), who lived for a long time in Morocco, stated that the gum exudes through incisions and becomes contaminated through running downwards. Johnston supposes that the stem of the plant is perforated by a beetle and that the gum exudes through the perforations and then hardens. According to Borszczow the young roots are especially rich in milky juice, which runs in large drops through cracks in the root bark, resulting from the prolonged heat of the soil, and is absorbed in the surrounding sand. Upon solidifying, it forms a very hard brown grey mass, which is exposed upon digging up the root. A very plentiful exudation of the juice also takes place between the bast bundles of the crown, and this forms an inferior brown variety of ammoniacum, much contaminated with sand, the so-called "gummi ammoniacum in massis." The gum resin which exudes at the axils of the flower-bearing branches and from the bases of the small umbels, as well as from the stem, is milk-white, presents a peculiar nacreous lustre, and is as soft as wax. It usually forms drops varying from the size of a pea to that of a nut, or even lumps ¼ to ½ inch in diameter. Exposed to the air the drops become covered with a yellow brittle crust.

4. *Commercial Varieties.*—Distinction is made between the African and Persian ammoniacum, only the latter of which at the present time appears in European commerce.

a. Persian ammoniacum.

(i.) Ammoniacum in grains, s. in lachrymis, s. in amygdaloides. Ammoniacum in grains or tears.—It consists of irregularly shaped, mostly roundish, pieces varying from the size of a millet seed to that of a walnut separated, or more seldom stuck together. The tears externally are of a pale yellow; or more or less reddish or brownish yellow colour, they have a dully waxy lustre, and are opalescent and opaque. Internally they are bluish or yellowish white, with a waxy lustre. They have a conchoidal fracture and in thin flakes or at the edges are translucent. At the ordinary temperature ammoniacum tears are hard and brittle, but readily soften in the hand, the more so the fresher the gum is. This kind is generally met with very pure, but nevertheless containing fruit, fragments of stem, etc.

(ii.) Ammoniacum in massis, s. placentibus, s. in panibus. Ammoniacum in mass, cake or bread.—Largish pieces, weighing one pound or more, of a dirty dark brown colour, with lighter spots. Sometimes the pieces have a marbled appearance from the alternation of dark and light portions. This sort is either softer than the preceding, smeary and sticky, or harder and more brittle, and more shiny and uneven at the fracture. Usually it contains fruit, stalk fragments, sand, and other impurities. Martiny describes a variety of this kind as containing very few impurities, and forming a conglomeration of whitish, reddish, yellow and greenish tears, mostly melted one into the other. This mass has a granite like appearance. Its smell is not like that of the ordinary kind, but very alliaceous and disagreeable, and it has a very bitter and acrid taste.

The Persian ammoniacum has a peculiar smell that has been compared to a mixture of garlic and castoreum, which is specially manifest upon heating or fracture; its taste is acrid and peculiar. Triturated with water it forms a white emulsion. When heated it melts slowly and incompletely. Spec. gr. 1·207. It dissolves in alcohol, 3 parts in 4, giving an acid solution.

b. African ammoniacum.

Pereira includes under this name* the viscous resin, which according to Lindley is yielded by *Ferula tingitana*, L., and which he considers to be the ἀμμωνιακόν of Dioscorides. He describes it as a light brownish, reddish, or, in parts, even bluish mass, which is soft, sticks easily to the fingers and smells quite differently to Persian ammoniacum. Hanbury also mentions this sort,† and says that the mother plant, according to Leared, is called in Morocco, "*Kelth.*"

As before stated, almost all the ammoniacum appearing in commerce in Persian. Most of it, according to Martiny, Henkel and Vigier, is imported through Bombay, but some comes direct from Persia. Vigier states that some passes through Bordeaux, whilst another portion goes from Persia through Astrachan into Russia.

African ammoniacum has only appeared twice in the London market, in 1857 and 1871. Hanbury says it was imported from Mogador. He also believed African ammoniacum to be still an article of commerce, not only in Morocco, but also in Egypt and Arabia, where it is carried by the Mecca pilgrims for use in fumigations.

GALICIAN OZOKERITE AND CERESINE.‡

BY DR. J. GRABOWSKY.

Ozokerite is found in Galicia (Austria) principally in Borislaw near Drohobycz, and Dzwiniacz near Stanistawow. Both places are situated at the northern foot of the Carpathian mountains; the formation is miocene, and of some importance on account of its petroleum springs. The production of "earth-wax" (ozokerite) was estimated to have amounted to about twenty million of kilogrammes in 1875, upwards of eighteen million of kilogrammes coming from Borislaw alone. According to F. v. Hauer, the largest crystals of salts, which are found in connection with the ozokerite, as well as the saline springs in the petroleum-bearing strata, prove that these latter belong to the zone of the calcareous neogene formation. They contain the fluid oil as well as the solid "earth-wax" partly in more or less regular beds, partly in fissures and pockets. The exploitation is affected by

* Elements 'Mat. Med' (1853) II., part 2, p. 1715.

‡ Read before the American Chemical Society, October 5, 1876. From the *American Chemist*.

means of shafts and tunnels, the former being from 40 to 80 metres deep and about 1 metre square, the latter being generally quite short on account of the very primitive method of ventilation and the great amount of gases. The shafts generally pass, first, through 8 to 10 metres of gravel mixed with boulders, then, through blue loam and plastic clay, which contains numerous layers of marl, slate, and sandstone. In this clay, usually at a depth of from 40 to 50 metres, petroleum springs and ozokerite are found. This latter forms lumps or layers from 1 to 3 feet thick, these lumps sometimes weighing several hundred kilogrammes. This native ozokerite is transparent, of pure honey-yellow colour, possessing the hardness of common beeswax. More frequently, however, ozokerite is found in thin layers and small pieces, which must be separated from the gangue; the smallest pieces are only obtained by a process of washing.

Besides pure, good "earth-wax," some varieties occur which are especially distinguished by hardness and colour.

The best "earth-wax" should have a pure yellow or greenish colour, and be easy to knead between the fingers; this, after having been tried (melted), yields a "prime" earth-wax, which is generally used for the manufacture of "ceresine." The poorer kinds are coloured black, and either very soft (containing much petroleum), or too hard, resembling asphaltum, fusing at a high temperature. After trying, these produce an "earth-wax" which is chiefly used for the manufacture of paraffin.

Occasionally there are found pieces of ozokerite, which are very compact, as hard as gypsum, fuse above 100° C., and are dichroitic (dark green in reflected and pure yellow in refracted light).

The composition of ozokerite is best expressed by the formula C_nH_{2n}. Very little is known about its formation. It appears to me to be very probable that it has to be considered as a product of the oxidation and condensation of petroleum hydrocarbons. Only lately we have seen that hydrocarbons, as, *e. g.*, naphthalene, can form by oxidation not products containing oxygen, but dinaphthil:

$$2C_{10}H_8 + O = C_{20}H_{14} + H_2O.$$

By supposing a similar oxidation of hexan or octan, we obtain compounds of the formula C_nH_{2n}, which again may condense with hydrocarbons of the marsh-gas series, and thus give rise to the formation of very complicated hydrocarbons of high melting point, *e. g.*:—

1. . . . $2C_8H_{18} + O_2 = C_{16}H_{32} + 2H_2O.$
2. . . . $C_{16}H_{32} + C_8H_{18} + O = C_{24}H_{48} + H_2O.$

By this hypothesis the formation of petroleum may be reduced to an oxidation of marsh-gas, and thus the close connection between ozokerite, petroleum, and coal be explained in the most simple manner.

As stated above, the crude ozokerite is separated from the gangue by melting, and worked into paraffin or ceresine. The trying is effected either by direct fire or by steam. In the former case, the ozokerite is placed into iron kettles of about one and a half metre in diameter by one metre in height, melted, drawn off, and the residue boiled with water, when all the ozokerite will rise to the surface of the water. In the latter case, the melting is done by steam in the same manner as with paraffin or stearin, and needs no further description. The tried ozokerite is clarified by allowing it to settle for several hours, and then poured into iron moulds. It is shipped in this form, without any further packing, and in pieces of about fifty to sixty kilogrammes.

There are principally two kinds of commercial ozokerite: prime and second. Prime "wax" ought to be as free as possible from earthy impurities and in small transparent, greenish-brown to yellow pieces; the lighter in colour and the more transparent, the better it is. "Second wax" is dark brown, almost opaque, occasionally containing a great deal of earthy impurities, and is generally much softer than the prime. Both are used for the manufacture of either paraffin and illuminating oils, or ceresine. The manufacture of paraffin from the ozokerite is effected by distillation over direct fire, from iron retorts with flat bottoms containing from 700 to 1000 kilogrammes. The products of the distillation are:—

Benzine	2 to 8	per cent.
Naphtha	15 „ 20	„
Paraffin	36 „ 50	„
Heavy (lubricating) oils	15 „ 20	„
Coke	10 „ 20	„

The paraffin is pressed, treated with sulphuric acid and caustic soda, filtered through paper and fine animal charcoal, and manufactured into candles. The naphtha is purified in the usual way, and the heavy oils are sometimes subjected to fractional distillation, but mostly shipped as such to Vienna.

The manufacture of ceresine consists of the removal of the impurities from the "earth-wax" by the aid of sulphuric acid and animal charcoal; but only the best kinds of ozokerite are used. The different processes are kept secret and are also protected by patents. In general, the ozokerite is melted with concentrated sulphuric acid and the residue from the manufacture of yellow prussiate, pressed, treated again with prussiate residue, and filtered. 100 parts good prime "earth-wax" yield 60 to 70 parts white wax, which in its properties very closely resembles white beeswax, and is called "ceresine." It is either further purified by repeated treatment with acid and prussiate residue, or coloured with gamboge or alkanet, and thereby made to closely resemble common beeswax. In the manufacture of ceresine only sulphurous acid and press residues are obtained, the former of which escapes into the air, but might be utilized, thus reducing the cost considerably. The consumption of sulphuric acid in Borislaw alone is said to amount to one million kilogrammes a year. The prussiate residues are obtained from the lixiviation of the crude prussiate in Moravia.

The finely divided animal charcoal seems to be the active agent, since a fair ceresine may be obtained by simply treating commercial "earth-wax" with bone char and concentrated sulphuric acid.

Comparatively only a small quantity of earth-wax is worked in Galicia; it is shipped principally to England, Moravia, and Vienna. The ceresine is exported in large quantities to Russia, where it is sold as beeswax; for this purpose it is melted together with a little beeswax, in order to impart to it the characteristic odour. Good ceresine is hardly to be distinguished from beeswax; the best methods are the following:—

1. Ceresine is not as easily kneaded between the fingers, and becomes brittle more readily than beeswax. This test is, however, doubtful, if the sample consists of a mixture of the two.

2. Ceresine is scarcely attacked by warm concentrated sulphuric acid, whereas beeswax is completely destroyed by it. By this test the quantities of beeswax and ceresine can be determined in a mixture of both.

In many cases ceresine can be employed in the place of beeswax. It is sold at from 32 to 40 dollars per 100 kilogrammes in Vienna, whereas the price of the commercial earth-wax varies from 10 to 12 dollars per 100 kilogrammes.

The whole exploitation of the ozokerite, on account of the want of enterprising men, is in the hands of the Jewish population. It is very imperfect, and necessarily requires many changes in the mining laws.

EMODIN FROM RHAMNUS FRANGULA BARK.*

BY C. LIEBERMANN AND M. WALDSTEIN.

Frangulic acid was first isolated by Faust from the bark of *Rhamnus Frangula*, and considered by him to be an anthracene derivative. With the object of comparing it more closely with the other isomers of alizarin—the authors used a substance which Dr. Merck had extracted for the purpose from a large quantity of frangula bark. The bark was exhausted with dilute soda ley, the extract precipitated with hydrochloric acid, the precipitate boiled with excess of soda ley, and again precipitated with hydrochloric acid. The washed and dried precipitate was dissolved in boiling absolute alcohol and then allowed to crystallize. Faust's method differs from this only in a purification through conversion into a lead salt before the crystallization.

Merck's substance, which was a red powder, appearing under the microscope in small needles, still contained an admixture of a glucoside, but the quantity was too small to allow of the preparation and determination of the sugar. After boiling with dilute sulphuric acid and three or four recrystallizations from alcohol or glacial acetic acid, the substance was obtained pure. From the acid it crystallized in beautiful silky orange-coloured needles, containing water and acetic acid, upon losing which at a temperature of 140° C. they became dull. In their characters these crystals agreed entirely with Faust's frangulic acid, except that no tables occurred with the needles, as in his observations.

Faust attributed to the air-dried frangulic acid, the formula $C_{14}H_8O_4+1\frac{1}{2}H_2O$, and stated that 1 mol. of water was lost at 120° C., but the other $\frac{1}{2}$ mol. only at 180° C. Therefore only a sample dried at above this temperature yielded him figures corresponding to bioxyanthraquinone (C, 70 p. c., and H, 3·3 p. c.), whilst the mean of five analyses of the compound dried at the lower temperature was C, 67·3 p. c.; H, 4 p. c. The authors' analyses of their purified compound constantly agreed very closely with the latter figures (Anal. I. and II.), even when heated to 190° C., by which the substance suffered a slight loss of weight through sublimation. A small quantity also was sublimed, the sublimate crystallized from absolute alcohol and dried at 150° (Anal. V.).

	I.	II.	III.	IV.	V.	Calculated for $C_{15}H_{10}O_5$.
C	67·0	67·4	66·7	67·2	67·1	66·7 per cent.
H . .	4·3	3·9	3·9	4·1	3·7	3·7 „

These results agreed very well with the formula of emodin ($C_{10}H_{15}O_5$); the carbon found was, however, a little too high (average 0·4 per cent.).

The authors obtained the acetyl compound of their substance by heating it at 180° C. with anhydrous acetic acid, purifying the product by treating it with dilute alkali as long as this was coloured after standing with it a little while. Upon crystallizing from alcohol, it was obtained in yellow needles, which melted at 193° C., and when dried at 115°, corresponded with the formula $C_{15}H_7(C_2H_3O)_3O_5$. This compound did not agree either in its external characters or its composition with the acetyl compound obtained by Faust.

An examination of the hydrocarbon resulting from the action of zinc dust, showed that it did not behave quite like anthracene, but exactly like the mixture of anthracene and methyl-anthracene obtained from emodin and chrysophanic acid. The melting point observed by Faust (195° to 200°) agreed well with that of methyl-anthracene.

The substance obtained by the authors from frangula bark agrees with emodin in the following characters:—The solubility, crystallization, and the colour of the solutions in alkalies are alike. Baryta and lime-water give red precipitates, which dissolve when boiled in water, giving it a slightly red colour. Alum solution gives with both only a yellow colour, and ammonia causes in these solutions a red precipitate. With the vapour of nitric acid they form a yellow nitro-compound, soluble in water with red colour. The crystalline needles of both remain shining at 100° C., and become dull at 140° C. Both compounds when completely dried and pure melt at 257° C.

The authors therefore consider that by their experiments, the presence of emodin in black alder bark has been established, and that it will be possible to obtain this costly substance, hitherto observed only in rhubarb, in larger quantity. Black alder bark, however, appears to contain only about 0·2 per cent. Faust's frangulic acid, especially judging from the acetyl derivative, they think is a different substance, probably a lower oxidation stage of their emodin, occurring side by side with it, like alizarin and purpurin. They therefore propose to seek it in the mother liquor of their compound. In the acetic acid mother liquor they have found a small quantity of a resinous body, fluorescent in alcoholic solution, and showing a characteristic absorption band, and to which the peculiar odour of the crude substance is due.

The bark used for these experiments was tolerably old, and it is quite concievable that during its storage an oxygen compound had gradually undergone further oxidation. This may perhaps be ascertained by examination of other specimens of bark.

The original glucoside of the bark, frangulin, also requires further investigation. Faust represents the formula and decomposition as—

$$\underset{\text{Frangulin.}}{C_{20}H_{20}O_{10}} = \underset{\text{Frangulic acid.}}{C_{14}H_8O_4} + C_6H_{12}O_6$$

This the authors believe to be wrong, as the decomposition would not result without water, and they suggest that the decomposition is probably as follows—

$$C_{21}H_{20}O_{10} + H_2O = C_{15}H_{10}O_5 + C_6H_{12}O_6$$

* 'Berichte der deutschen chemischen Gesellschaft,' i p. 1775

THE NUTRITION OF PLANTS.

The Italian botanist, Professor Cugini has recently contributed to the Italian Journal of Botany an exhaustive paper on the alimentation of cellular plants. The view most generally adopted with regard to the relative value of the different elementary substances contained in the soil for the nutrition of plants, is that stated by Sachs in his 'Text Book of Botany' (English edition, p. 619), who arranges them in three series, in their order of importance, thus:—

Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur.
Potassium, Calcium, Magnesium, Iron.
Phosphorus, Chlorine.

Professor Cugini distributes them into five series instead of three:—

Carbon, Hydrogen, Oxygen, Nitrogen.
Sulphur.
Potassium, Phosphorus.
Iron, Magnesium.
Silicon.

In order, however, for these elements to become useful to the plant for purposes of nutrition, they must first be combined into proximate food-materials soluble in water or in very dilute acid. These substances he arranges in the following table:—

Necessary	Organic carbon-compounds. Water. An ammoniacal salt. Sulphates of potassium and iron. Phosphate of magnesium. An alkaline silicate.
Occasional	Chloride, Iodide, Bromide } of sodium or potassium. Phosphate, nitrate, or sulphate of calcium, salts of zinc, manganese and aluminum.

The author discusses at length the much vexed question of the part played by potassium in the vegetable economy He considers its function to be altogether different from that of any other elementary body, and to bear a somewhat similar relation to the production of the carbo-hydrates to that which phosphorus bears to the production of the albuminoids. Calcium he does not regard as an indispensable element. Iron must, however, be so considered, from its peculiar relationship to the colouring matter of chlorophyll. He is unable to assign any special function to magnesium, although it appears to be essential.

ACIDUM PHOSPHORICUM DILUTUM.*

BY RICH. V. MATTISON, PH.G.

To the average reader it seems hardly possible that anything new can be said on this subject, so thoroughly has it been discussed and this discussion commented upon by recent writers. The U. S. Pharmacopœia directs either of two processes, directing preferably the oxidation of phosphorus by nitric acid, and the subsequent dilution to the proper specific gravity. The objection to this process, we believe, comes from only one source, viz., the retail druggist, to whom it is both dangerous and insufferably tedious, requiring constant watchfulness regarding temperature, "eternal vigilance" being the only price of safety, besides being a source of constant expense through the breakage of funnels, capsules and the other paraphernalia of the phosphoric acid apparatus usually found at the command of the pharmacist. It is, however, the process usually followed by manufacturers, because of its most striking allurement, viz., cheapness; and for their benefit we will describe a piece of apparatus employed by ourselves for the past two years in the manufacture of this preparation.

We place in the yard attached to the laboratory a tub of twenty-five gallons capacity, into which we place some smooth bricks, and upon these we place a graphite crucible, of say ten gallons capacity, such as are used in the steel works for melting and refining of cast steel, and upon the top of this we insert a funnel and carefully lute the edges with flaxseed meal or clay—having previously placed in the crucible the quantity of phosphorus we wish to convert into phosphoric acid. Into the spout we place a glass tube reaching to the bottom of the crucible, and at the apex insert a small funnel; the apparatus is now complete with the exception of the method of applying heat.

On the upper floors of the laboratory are the steam-pans from which the condensed steam passes through the drip-cock, either to the boiler tank or to the ground below. Now we take a small steam-pipe and attach one extremity to the drip-cock and allow the other to terminate into the tub in which stands the acid apparatus. We start the process by putting the phosphorus into the crucible, luting the funnel as before described, and through the tube in the spout, adding the quantity of nitric acid, slightly diluted, that may be requisite. We then allow the condensed steam to fill the tub, and pay no more attention to it excepting to add water or nitric acid as occasion may require. Through the daily use of the steam-pans, stills, etc., there is abundance of condensed and live steam passing into the tub, the water in which is thereby kept constantly hot, without requiring any attention, and the process may go on for weeks without the slightest danger or annoyance to the motive power, which is furnished at a minimum of expense by the waste product (condensed steam) which would be utilized for no other purpose.

A note here regarding the practical working of the first process by the pharmacist. The case in point is this: We had occasion some time ago to drop into the store of a gentlemen well known for his pharmaceutical attainments, and who makes it an item of especial pride that "he prepares his dilute phosphoric acid from phosphorus direct." Well, at the time of our call we beheld the "youngest apprentice," we judged from the exceedingly crude methods of manipulation he practised, at work on the officinal process in question. To say "he took no note of time" is inapplicable, but that he took no note of *temperature*" certainly is, for his chief design seemed to be to burn the largest amount of phosphorus in the shortest possible time—the phosphorus being mostly on fire, and dense clouds of phosphoric anhydride issuing from the mouth of the funnel escaped up the chimney besides clouding the atmosphere of the store. Upon our modestly offering the suggestion that the proper place for the anhydride was in the capsule instead of the atmosphere, the proprietor rather curtly informed us that "Oh, he (the youngest apprentice before referred to) knows all about it; *he's made it before.*"

These are the facts; the commentary is that if an educated pharmacist is unable to prepare phosphoric acid by this process without losing 50 per cent. of the anhydride, the acid thereby being proportionately reduced in strength, then the process is not a proper one to be left in the hands of druggists generally for the manufacture of this preparation.

The second process of the Pharmacopœia is unsuitable, and should not, on any account, be followed, because of the fact that all the metaphosphoric acid of the United States market is contaminated with quantities varying from 15 to 35, or more, per cent. of sodic phosphate, which is added to the pure metaphosphoric acid by the German manufacturers for the purpose of causing it to concrete into those beautifully transparent, solid masses, in which shape it is more easily handled commercially.

The objections to this process then are very grave ones, viz., that the metaphosphoric acid is largely contaminated with sodic orthophosphate which, upon heating is converted into pyrophosphate, and the resulting acid formed by following the Pharmacopœia process is not only deficient in strength, which varies accordingly with the amount of sodic salt contained therein, but the presence of the pyrophosphate precipitates the corresponding ferric salt when the acid is added to solutions containing iron.

A third process, which is known as "Markoe's process," consists in acting upon phosphorus with bromine in the presence of water. With care the process is esteemed a safe one, but the fact remains that at least one experienced experimenter has had proof positive of the contrary, and we would not recommend the process as one to be left in the hands of the inexperienced, though that it does furnish excellent results at a limited cost is undeniable.

The fourth process is the one we propose for the next Pharmacopœia. It is not designed for the manufacturer, but for pharmacists. Its chief feature is simplicity, combined with ease and rapidity of execution. Its simplicity depends upon the ease with which amorphous phosphorus is converted into orthophosphoric acid by the action of nitric acid, and we would propose the following modification of the first officinal process:

Take of Phosphorus (amorphous) 370 grains.
Nitric acid . . . . 5 troyounces or q. s.
Water, sufficient quantity

Add the nitric acid to eight fluidounces of water in a porcelain capsule, and to this add the amorphous phosphorus; raise the temperature of the mixture to boiling, and evaporate until the solution has lost the odour of nitric acid. (It would be almost superfluous to caution the operator at this period regarding the passage of ortho- to pyro-phosphoric acid by increased temperature.) When perfectly free from nitric acid it should be diluted to the measure of twenty fluidounces, or to the requisite specific gravity, the arsenic and other impurities, if present, having been previously removed.

* Read at the Pharmaceutical Meeting of the Philadelphia College of Pharmacy, December 19th. From the *American Journal of Pharmacy*.

Of a sample of acid prepared by this process one hundred grains were neutralized by twenty-four and six-tenths grains of perfectly dry crystals of acid potassium carbonate; solution of ammonic nitrate gave a yellow precipitate; it did not coagulate albumen or precipitate with tincture of the ferric chloride when mixed in various proportions.

The operation is finished in fifty minutes, and if judicious note of temperature is taken the finished product is free from pyro- or meta-acids, perfectly free from danger either to person or property, no gauze spectacles or additional insurance, a process that the youngest apprentice cannot blunder over; easy, efficient and economical, what more could be desired?

OIL OF CINNAMON LEAVES.*

BY N. A. KUHN.

This oil has a sharp, biting taste, with an odour reminding at first very faintly of nutmegs, afterwards strongly of cloves, but if heated with KHO that of cinnamon is predominant. The colour is near that of true oil of cinnamon, and the specific gravity is about the same, it being a little heavier than water, sinking when put in that liquid.

It does not fulminate with iodine, does not give any colour with nitro-prusside of copper, nor with hydrochloric acid; with nitric acid a brown colour similar to an iodine stain; with sulphuric acid a violet purple, which is turned brown by nitric acid, as the oil treated with the latter alone is.

A portion was treated in a test tube with a small portion of sulphuric acid and potassium bichromate. In the vapours from this a piece of bibulous paper that had been dipped first in guaiac tincture, then in a weak solution of cupric sulphate, was turned blue, showing the presence of hydrocyanic acid. Care was taken that the oxidizing agent was not in excess, else the benzoic aldehyd, which was generated from the cinnamic acid contained in the oil, would be converted into benzoic acid, which is odourless, and would not give any reaction in the state of vapour.

This reaction, showing the presence of cinnamic acid, was obtained from the distillate of the next also.

Another portion of the oil, after adding some potassa, was heated and the vapour condensed. The part remaining was treated with dilute hydrochloric acid and filtered. To the filtrate nitric acid was added and the liquid concentrated, when a reddish-brown resin and star-shaped crystals, resembling oxalate of ammonium, were obtained.

A solution of the crystals yielded a precipitate with calcium chloride which was insoluble in acetic acid, but soluble in hydrochloric acid, showing an oxalate. This with the brown resin indicates that eugenic acid ($C_{10}H_{12}O_2$) was present.

When the nitric acid was added, an odour so familiar was produced that it took some time to place it. It was that of aromatic vinegar, indicating that acetic acid was also among the products of the decomposition of residue left in the test tube.

MERCURIC PEPTONE AS A SUBSTITUTE FOR THE PROPOSED MERCURIC ALBUMINATE.†

Albuminate of mercury was introduced into medical practice not quite one year ago,‡ and it appears to have already found a substitute in the so-called "Mercuric Peptone." Prof. H. v. Bamberger, who originated the abulminate, found that it was not merely difficult to prepare a clear and pure solution of this compound, but that it was moreover rather liable to spoil by keeping. He therefore replaced the albumen by a substance nearly related to it, namely, peptone. This latter body is easily soluble in water, resists the effects of heat, alkalies and salts, may be easily filtered, and forms a compound with mercury without difficulty. To prepare the latter, it is necessary to first make a solution of mercuric chloride (corrosive sublimate) of exactly five per cent., and a solution of sodium chloride of twenty per cent. One gramme of meat-peptone is dissolved in 50 c.c. of water, and 20 c.c. of the mercuric chloride solution are added. This produces cloudiness, which is removed by the further addition of 15-16 c.c. of the sodium chloride solution. The finished liquid contains one per cent. of mercuric peptone. The results of all trials which have thus far been made with this preparation are very satisfactory.

TREATMENT OF RINGWORM BY LEAVES OF CASSIA ALATA.*

BY DAVID FOULIS, M.D.,

Lecturer on Pathology, Glasgow Royal Infirmary School of Medicine.

When resident in India (Cachar) many years ago, I had numerous opportunities of observing a form of vesicular ringworm which afflicted both natives and Europeans. It commenced by a minute cluster of vesicles on the skin, soon extending in the form of a ring, or segment of a ring, the centre being left free; it was very itchy, and the scratching which this induced left the little vesicles torn, and the surface raw and weeping, or else covered with scabs. Not a few of the tea-planters of the district caught the disease; and they resorted to various remedies, the favourite one being the ointment of the red iodide of mercury, applied so as to blister the skin. This gave a temporary relief at the cost of a good deal of suffering, especially if the surface affected were large. But none of the remedies in use there could at all compare for efficacy with the native remedy. This consisted in the fresh leaves of the *Cassia alata*, called in Hindostanee the "daod patta." A few of the leaves were taken and vigorously rubbed over the diseased area until the leaves were torn to fritters; the expressed juice was left to dry on the skin, which it stained for the time of a light brown colour. The effect invariably was, that the itching at once disappeared, and that in a day or two the skin was restored to its normal healthy aspect. The process of rubbing was by no means painful; on the contrary, the patients seemed rather to feel an indefinite pleasure from it. So useful did I find this remedy, that I procured some cuttings of the plant, and planted them in the vicinity of my bungalow; and many a time have I had the pleasure of relieving those suffering from this annoying disease by the gift of a handful or two of these leaves.

I may mention, by the way, that the imported coolies in the tea-gardens did not suffer so much from the ringworm as the native Cachar villagers. I remember treating one of the latter, whose whole bodywas covered with it; and a few applications of the leaf effected a cure, which I believe was permanent.

It would be interesting to learn whether the Goa powder, recommended by Sir J. Fayrer, contains these leaves in any form; and also, whether their active principle has any affinity with the chyrsophanic acid which Mr. Squire finds so useful in psoriasis. The *Cassia alata* belongs to the same genus as the senna plant, and experiment might reveal some analogy in their therapeutic actions; but I am not aware of any trials of the leaves having been made except as a remedy for ringworm.

* From the *British Medical Journal*, January 20, 1877. The author calls this plant "*Cassia lata*" in the original paper, no doubt in error for the *Cassia alata*, which is included in the Indian Pharmacopœia.—Ed. P. J.

The Pharmaceutical Journal.

SATURDAY, JANUARY 27, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, *17, Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary, 17, Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

WHAT IS ADULTERATION?

UNDER the title "What is Adulteration?" the *British Medical Journal* has published an article, which appears to be the first of a series intended to elucidate this question, and, *apropos* of the Runcorn case, milk of sulphur has unhappily been selected as the starting point of the discussion. The whole tenour of the writer's remarks indicates that he entertains a decided opinion in favour of restricting the term "milk of sulphur" to the preparation of sulphur ordered in the British Pharmacopœia under the designation of precipitated sulphur. Having his mind possessed by this idea it is both natural and necessary that he should come to the conclusion that the other preparation, about which there is so great a difference of opinion, is an adulterated article.

Beyond affording an illustration of the self-satisfaction with which a fallacy may be propped up by this circular style of argument we fail to perceive that the article in the *British Medical Journal* has done anything to throw light on the question whether the sale of the "milk of sulphur" prepared according to the directions of the Pharmacopœia of 1721 is, or is not, a breach of the law.

It is true the article contains a number of *ex cathedrâ* affirmations, let off with all the assurance requisite for concealing their want of sound foundation in fact; but there is neither evidence nor argument to support them. The evidence given on the Runcorn case, to the effect that the sulphur was rendered much more beneficial by the presence of hydrated calcium sulphate, is disposed of simply by calling it "remarkable," and attaching a note of admiration; but this mode of procedure is scarcely sufficient to dispose of the facts upon which that evidence is based. Again sulphate of lime is pronounced to have no medicinal properties, though we are not favoured with a statement of the grounds upon which this assertion is made. Only a few lines further on, with striking inconsistency, this substance is stated to cause constipation and other unpleasant symptoms when taken internally as an ingredient of some hard waters. This statement we believe to be incorrect, for so far as our experience extends the efficacy of sulphate of lime in hard drinking water is manifested in a precisely opposite manner.

The writer of the article in the *British Medical Journal* has also carried his disregard of fact to the extent of misquoting our report of the Runcorn case, by stating that we described the article sold as milk of sulphur, as actually containing "plaster of paris," and having dragged in this sensational peg, he proceeds to hang upon it an appropriately flimsy argument that milk of sulphur containing sulphate of lime is the precipitated sulphur of the Pharmacopœia in an adulterated form, and it is suggested that the more correct name would be "plastered sulphur."

We regret our inability to designate this language as being either "learned," or altogether honest. The merest tyro in chemistry knows well enough the difference between plaster of paris and the sulphate of lime contained in the "milk of sulphur," and the use of the term plaster of paris in relation to this preparation can only be ascribed to ignorance or unfairness. We will not pursue this point further than to suggest that whatever may be the advantage to be gained by introducing the ideas associated with plaster of paris, it is a means of influencing opinion more adapted for a police court attorney than for a journal representing the medical profession.

It is not less unfair to represent the sale of milk of sulphur as being instigated by fraudulent motives, and in our opinion it is an unworthy course which the writer in the *British Medical Journal* takes when he says:—"Hence profit and loss enter largely into the selection of the compound for sale, and we are, therefore, not surprised that the Chemists and Druggists' Trade Association should take up the defence with such zeal and earnestness." This uncompromising insinuation is based upon the consideration that if hydrochloric acid were used in the decomposition of calcium sulphide the druggist would lose his acid and lime, while if he used sulphuric acid he would utilize them and sell them as sulphur. Probably most of our readers are sufficiently acquainted with the relative value of the materials here in question to appreciate the cogency of such argument, and it would be unworthy of notice if it were not that by its speciousness it carries some weight with persons ignorant of chemistry and prone to be infected by such mental "disease germs."

The contention that "milk of sulphur" containing sulphate of lime is not an article of the nature, substance, and quality demanded by the purchaser because it contains no milk is unaccountably frivolous. With as much reason hepar sulphuris might be objected to because it contained no liver. Again the asserted indigestibility of the sulphate of lime might probably be urged against the sulphur itself, with at least as much reason. Those who defend the sale of milk of sulphur do so upon the ground that it is a familiar article, and one for which there is a decided preference with many persons who also object to the precipitated sulphur.

The presence of sulphate of lime in it is a necessary consequence of the method of preparation authorized by the Pharmacopœia Revision Committee in 1746, and whether the preparation be included or not in the present Pharmacopœia, that fact is sufficient to bring it within the terms of the exceptions provided for in the Sale of Food and Drugs Act, since the sulphur is in the process of preparation unavoidably mixed with sulphate of lime. Whatever objection, real or imaginary, there may be in the minds of some persons to the presence of sulphate of lime, it is at least unfair to call it an adulteration, and still more to call it fraudulent. Precipitated sulphur can readily be obtained by those who desire to have it, and we cannot perceive why those who desire to have the other preparation should be debarred from doing so.

We trust that our contemporary in pursuing the discussion of the question "What is Adulteration?" will in future be more fortunate in the selection of subjects and methods of dealing with them. The question is one well deserving consideration from various points of view, and there is room for rendering good service, not only to the public at large, but also to the trading community, by carrying it out with impartiality and a due regard to the inexorable logic of fact.

LEAD PIPES.

A SHORT time since it was stated that the symptoms of lead poisoning observed in a patient received into one of the London hospitals were traced to their source in the pipes of the public house patronized by him. The man, being an early riser, was in the habit of drinking a glass of spirit as soon as he could obtain it, and being generally the first customer, received it from the publican contaminated, it was affirmed, with a certain quantity of lead that it had dissolved whilst in contact with the pipes during the night. A similar matter seems to have also occupied the attention of the Medical Society of Ghent. In the report just issued of a committee, of which DR. MOREL is the reporter, it is stated that cases of saturnine poison are very frequent in Ghent among adults, and that in many cases it has been recognized in persons who are in the habit of frequenting the *cafés* and *estaminets* early in the morning, and drinking beer that has possibly lain in contact with the leaden pipes of the beer engine during the night. After referring to an investigation of Meurin in 1853, which led the French Government to issue a decree prohibiting the use of pipes of lead, copper, or zinc, or of tin containing more than 16 per cent. of lead, in connection with beer engines, the committee expresses its adhesion to the principle of the French decree, and recommends the Ghent Medical Society to take the initiative in impressing upon the Belgian authorities the necessity of dealing with the question immediately.

MUNICIPAL.

AT a special meeting of the Town Council of Cambridge, held January 18, MR. ARTHUR DECK, the Local Secretary of the Pharmaceutical Society, F.C.S., was unanimously elected an Alderman of the Borough in the place of MR. C. E. BROWN, J. P., deceased. We believe it is the first occasion within the memory of the oldest inhabitant of one of our pharmaceutical brethren occupying a seat upon the aldermanic bench in Cambridge.

Transactions of the Pharmaceutical Society.

PRELIMINARY EXAMINATION.

A meeting of the Board of Examiners for England and Wales was held on Wednesday, January 24, 1877.

Present—Mr. Williams, President; Messrs. Allchin, Barnes, Carteighe, Gale, Haselden, Martindale, Moss, and Taylor.

The Report of the College of Preceptors on the Preliminary Examination held on January 8 was received.

Two hundred and seventy seven candidates had presented themselves for examination, of whom *one hundred and twenty five* had failed. The following *one hundred and fifty two* passed, and the Registrar was authorized to place their names upon the Register of Apprentices or Students:—

(Arranged alphabetically).

Adamson, Joseph William ......Epworth.

The Questions for Examination were as follows:—

First or Preliminary Examination.

January 8th, 1877.

(*Time allowed: Three hours for the three subjects.*)

I. Latin.

1. Translate into English:—Dum hæc in colloquio geruntur, Cæsari nuntiatum est equites Ariovisti propius tumulum accedere et ad nostros adequitare, lapides telaque in nostros conjicere. Cæsar loquendi finem facit, seque ad suos recepit, suisque imperavit, ne quod omnino telum in hostes rejicerent. Nam etsi sine ullo periculo legionis delectæ cum equitatu prœlium fore videbat, tamen committendum non putabat, ut, pulsis hostibus, dici posset eos ab se per fidem in colloquio circumventos.

2. Decline *hæc, lapides, telum*; and together, *ullo periculo*.

3. Account for the cases of *equites, tumulum, hostes, periculo, legionis*, and for the mood of *posset*, in the passage above.

4. Give the present, the perfect, the infinitive, and the supine of *accedere, rejicerent, facit, recepit, putabat, videbat.*

5. Define an Ablative Absolute, and give two examples.

II. Arithmetic.

[The working of these questions, as well as the answers, must be written out in full.]

6. What number subtracted from three hundred and sixty-five millions twenty-seven thousand and forty-five, will leave eighty-four thousand two hundred and six?

7. A bankrupt's debts are £5760, he is able to pay 12*s.* 0½*d.* in the £; find his assets. How much will a creditor to whom he owes £48 10*s.* lose?

8. Simplify:— $(3\frac{3}{20} \times 15\frac{4}{7}) - \left(\frac{2}{3\frac{3}{4}} \div \frac{2\frac{3}{4}}{3}\right)$.

9. Reduce $\frac{17}{256}$ and $\frac{1}{101}$ to decimals; and find the value of 36·42 tons at 17*s.* 7¼*d.* per ton.

10. What will be the cost of glazing a window containing 60 squares, each 1 ft. 3 in. long, and 11¼ in. wide, at 5*s.* 4*d.* per square foot?

III. English.

11. Define the term *Pronoun*. What is meant by *personal, relative,* and *demonstrative* pronouns? Give the objective cases of the pronouns *I, he, it, me, they, who.*

12. In what ways may the feminine of nouns be formed from the masculine in English? Give the feminine forms of the following nouns:—*author, duke, hero, king, czar, executor, earl, nephew, he-bear, turkey-cock.*

13. Parse the following lines:—

"A sensitive plant in a garden grew,
And the young winds fed it with silver dew."

14. Give a sketch of the life of Queen Elizabeth, *or* Charles I., *or* Oliver Cromwell; *or* write a short account of the late Arctic Expedition.

The following is a list of the Centres at which the examination was held, showing the number of candidates examined at each Centre, and the result:—

	Candidates.				Candidates.		
	Examined.	Passed.	Failed.		Examined.	Passed.	Failed.
Aberdeen	6	4	2	Leicester	3	2	1
Aberystwith	1	1	0	Lincoln	8	4	4
Barnstaple	1	1	0	Liverpool	10	7	3
Birmingham	12	7	5	London	39	16	23
Boston	1	0	1	Lynn	2	2	0
Brighton	3	2	1	Macclesfield	2	1	1
Bristol	7	4	3	Manchester	14	6	8
Cambridge	4	2	2	Newcastle	9	5	4
Canterbury	3	2	1	Northampton	3	1	2
Cardiff	4	2	2	Norwich	10	5	5
Cardigan	2	2	0	Nottingham	6	2	4
Carlisle	5	4	1	Oxford	2	0	2
Carmarthen	2	1	1	Perth	1	1	0
Carnarvon	4	3	1	Peterborough	3	2	1
Cheltenham	1	0	1	Plymouth	5	4	1
Chester	3	2	1	Portsmouth	2	1	1
Colchester	1	0	1	Preston	9	6	3
Darlington	8	3	5	Reading	2	1	1
Doncaster	2	2	0	Scarborough	1	1	0
Dundee	6	4	2	Sheffield	3	1	2
Edinburgh	13	6	7	Shrewsbury	3	1	2
Exeter	3	1	2	Stafford	2	1	1
Glasgow	11	6	5	Swansea	6	6	0
Hereford	2	1	1	Taunton	1	0	1
Hull	5	4	1	Truro	3	3	0
Leamington	1	1	0	Worcester	1	1	0
Leeds	10	4	6	York	6	3	3

The following Certificates were received in lieu of the Society's Examination:—

Certificate of the College of Preceptors.

Braithwaite, John Oldham ......London.

Certificate of the Royal College of Surgeons of England.

Billinton, Arthur ....London.

Certificate of the University of Cambridge.

Rookledge, Francis Eyre.........Easingwold.

Provincial Transactions.

GLASGOW CHEMISTS AND DRUGGISTS' ASSOCIATION.

The third meeting of the session of this Association was held on the evening of Wednesday, 17th January last. In the unavoidable absence of the President (Mr. Frazer), Mr. Kininmont, Vice-President, occupied the chair.

After the usual preliminary business was disposed of, Dr. A. T. Machattie, F.C.S., etc., was called upon, and delivered a most interesting and instructive lecture, the first of a course of three, on "Modern Chemistry," the subject being treated in its general relations to all the other natural sciences.

The lecturer began by discussing the various theories held by ancient and modern philosophers regarding the existence or non-existence of what we understand by the term *matter*. Assuming its existence, the divisibility, finite or infinite, was then commented on, with reference especially to the atomic theory. *Inertia*, or the absence of any power in matter to spontaneously change its position or condition, coupled with the obvious fact that matter is not at rest, led to the meaning of what is now known as *motion* or *force*, and the domain of natural science shown to be limited to a consideration of *matter* and *force*. It was stated that many kinds of matter and many kinds of force exist, but however much the appearance of the former or direction of the latter may vary, matter and force are equally indestructible. If matter could be created or annihilated by any human means, or if motion could originate in or proceed from nothing, or lapse into nothing, no science of chemistry could possibly exist.

The different kinds of motion in matter, *i.e.*, movements of masses of homogeneous molecules and of heterogeneous molecules were next considered. The last-named being referred to as the special province of chemistry.

The lecture concluded by a sketch of some of the happy guesses at truth made by the alchemists and other early philosophers, which in some instances come so near to the most advanced theories of modern natural science.

The lecture was listened to with marked attention, many of the points being loudly applauded, and at the close the customary vote of thanks was cordially given to Dr. Machattie.

The second lecture will be given on the 31st inst.

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, January 18, 1877, Professor Odling, F.R.S. Vice-President in the chair. After the names of the visitors had been announced, and the minutes of the previous meeting read and confirmed, the following names were read for the first time:—Messrs. Michael Conroy, A. Pearson Luff, A. W. Glover, J. Angell, J. Bardsley, and M. Algernon Adams. Messrs. William Harrington, John Comyns Leach, and the Rev. D. W. Sadler, were ballotted for and duly elected, after their names had been read the third time.

The first paper, by Dr. E. Jäger, "On Some Derivatives of Dithyamyltrichlorethane," was read by the Secretary. The author prepares the substance by the action of sulphuric acid diluted with one-third its volume of acetic acid on a mixture of chloral (one molecule), and thymol (two molecules). It forms colourless monoclinic crystals, melting at 198°, and by the action of oxidizing agents is converted into thymoquinone. Dithymyltrichlorethane, $Cl_3CH\langle{}^{C_{10}H_{12}OH}_{C_{10}H_{12}OH}$ when heated with zinc dust yields dithymylethane $CH_3CH\langle{}^{C_{10}H_{12}OH}_{C_{10}H_{12}OH}$ and dithymylethene $CH_2{=}CH\langle{}^{C_{10}H_{12}OH}_{C_{10}H_{12}OH}$ the former crystallizing in flat plates, which melt at 180°, and the latter in needles, melting at 170°. By the action of feeble oxidizing agents it yields a green crystalline compound, *dithymylquinhydroethene*, $CH_2{=}C\langle{}^{C_{10}H_{12}OH}_{C_{10}H_{12}O} \; {}^{OH\,H_{12}C_{10}}_{—\;O\,H_{12}C_{12}}\rangle C{=}H_2C$ which by the further action of the oxidizing agent is transformed into a red substance, *dithymylquinonethene*, $CH_2{=}C\langle{}^{C_{10}H_{12}O}_{C_{10}H_{12}O}\rangle$ these are related to one another, and to the parent hydrocarbon in the same way that green quinhydrone and quinone are related to hydroquinone.

The Chairman said the fellows were much indebted to the author for introducing to their notice these complex compounds related so nearly to the quinones.

Dr. Armstrong said the experiments of Dr. Jäger possessed considerable interest, and although he agreed with him as to the formula he had assigned to the quinone, he could not say as much for that attributed to the green crystals, for it must be remembered that in the formation of green quinhydrone three molecules of quinone took part, and not two, so that it was highly probable that the author's green compound should be represented as derived from three molecules of quinone, and not two only.

The next paper "A Preliminary Account of Some New Reactions in Organic Chemistry, and their ultimate bearings," by Mr. C. T. Kingzett and Dr. H. W. Hake, was read by the former. After referring to the colour reactions known as the "Pettenkofer reaction," produced by the action of strong sulphuric acid on a mixture of sugar and cholic acid, and some other substances, as glycocholic, hyocholic, oleic and lithofellic acids, etc., and various compounds occurring in brain substance; the authors state that they have found that many other bodies behave in a similar manner, as benzene, phenol, turpentine, camphor, salicylic acid, pyrogallol, piperin, morphine, clove and other essential oils and various fatty bodies. Camphor dissolves in concentrated sulphuric acid, forming a deep red solution, and this when mixed with cane sugar syrup solidifies to a rose-coloured paste, but on adding water the colour is destroyed, and an almost colourless precipitate produced, which is soluble in ether. When treated with sulphuric acid it now gives the colour reaction without the addition of sugar, although even when boiled for several hours with dilute sulphuric acid, no sugar could be detected in the solution, in which this substance differs in a marked manner from the ordinary glucosides. From a comparison of the reactions yielded with the Pettenkofer test by benzene, benzoic acid, and phenol on the one hand, and turpentine, camphoric acid, and camphor, on the other, the authors are of opinion that camphor stands in a somewhat similar relation to turpentine that phenol does to benzene, and camphor indeed may be the phenol of turpentine, and not a ketone as ordinarily supposed. The authors concluded with some observations on the ultimate bearings of these new reactions, which they consider to cover a very wide field, leading, for instance, to the question of the general constitution of sugar and similar substances. Some of the reactions mentioned in the paper were exhibited.

Dr. Odling having thanked the authors for their interesting paper, Mr. C. E. Groves asked whether they considered the new compound obtained with the camphor solution and sugar to be of the nature of a glucoside, or whether the cane sugar which they employed was converted into glucose.

Mr. Kingzett replied, that from the difference observed when such bodies as mannite were substituted for sugar in the reaction, he considered it probable that glucose might be found. The compound, however, was not an ordinary glucose or saccharide, as it was not decomposed by boiling with dilute acids; he believed, however, it would prove to be of the nature of a substitution derivative of a hexatomic alcohol $C_6H_8(OH)_6$, in which one or more OH groups were replaced.

Dr. Armstrong said they were much indebted to the authors for bringing before their notice these interesting colour reactions, but he thought the facts adduced as yet did not justify the speculative conclusions which they had shown, as for instance, that the relation between camphor and turpentine was similar to that between phenol and benzene.

Mr Kingzett replied, that although he had not done so, he could give structural formula to illustrate his meaning, and proceeded to show how some of the brain substances were split up under the action of sulphuric acid, when they gave this colour reaction. With regard to the relation between turpentine and camphor, he considered there was strong evidence to prove that camphor was a phenol, and comparatively little to show that it was a ketone. The relation was brought out distinctly, on comparing the formulæ.

Benzene C_6H	Turpentine $CH_3\ C_3H_7\ C_6H_6$
Phenol $C_6H_3\ OH$	Camphor $CH_3\ C_3H_7\ C_6H_6\ OH$

Dr. Wright remarked, that although one argument in favour of the hydroxyl nature of camphor was its behaviour with such reagents as zinc chloride and phosphorus pentasulphide, giving rise to cymene, yet on the other hand, with phosphorus pentachloride, it yielded dichlorinated derivatives, which was not in accordance with the ordinary behaviour of alcohols under similar circumstances.

The next paper on "Dinitroso-orcin and Dinitro-orcin" by Dr. J. Stenhouse, F.R.S., and Mr. C. E. Groves, was read by the latter. The authors, after some preliminary remarks on the nitroso-compounds, described the method for the preparation of dinitroso-orcin, $C_7H_4(NO)_2(OH)_2 + 2OH_2$, which consisted in adding a solution of nitrosyl sulphate, NO,HSO_4, in strong sulphuric acid, to a dilute solution of orcin when the nitroso-orcin was deposited after a short time as a yellowish brown powder. It was purified by suspending it in alcohol, and converting it into the ammonium compound by the cautious addition of alcoholic ammonia. The green crystals thus produced are collected, pressed, and decomposed by dilute acid; a repetition of the process suffices to render the nitroso-orcin pure. In this state, it is a pale-coloured crystalline powder, insoluble in water, alcohol, ether, benzene, etc., but decomposed by boiling with alcohol. It forms green crystalline salts with potassium, sodium, and ammonium, but those of the alkaline earths and heavy metals are brown amorphous precipitate.

Dinitro-orcin, $C_7H_4(NO_2)_2(OH)_2$, strong nitric acid converts nitroso-orcin into trinitro-orcin, but with dilute nitric acid in the cold it yields dinitro-orcin. This crystallizes in deep yellow rhomboidal plates, which melt at 164°.5 C, and may, with care, be sublimed at a higher temperature. Heated rapidly on platinum foil, it deflagrates. Dinitro-orcin is almost insoluble in cold water, moderately soluble in cold alcohol, and readily in ether. The alkaline salts of dinitro-orcin crystallize with difficulty, but with barium it forms compounds, one, of a deep crimson colour, and insoluble in water, which is basic, the other having the composition $[C_7H_4(NO_2)OH]_2\ BaO_4 + OH_2$ is sparingly soluble in boiling water, but crystallizes out almost completely on cooling, in long silky needles of a brilliant orange colour. The authors also find that nitrosyl sulphate may be advantageously employed in the preparation of nitroso-phenol, nitroso-thymol, nitroso-naphthol, and dinitroso-resorcin. This paper was experimentally illustrated.

The Chairman having thanked the author, the Secretary read a paper by Dr. T. Carnelley "On High Melting Points, with Special Reference to those of Metallic Salts, Part III." The author has determined the "time values" of nine standard salts, by comparing the time of melting with that of sulphur; the times of melting of the different salts always bearing a constant ratio to one another and to sulphur, and this ratio is the true value for each given salt. By interpolation, the author has constructed a table giving the melting points corresponding to various time values from 0 to 241.

After the Chairman had thanked the author in the name of the Fellows, he adjourned the meeting until Thursday, February 1, when there will be a paper by Dr. H. E. Armstrong, "On Kekulés and Ladenburg's Benzene Symbols," and one on the formation of coumaric, cinnamic, and other analogous acids, from the aromatic aldehydes, by Mr. W. H. Perkin.

Parliamentary and Law Proceedings.

THE SALE OF FOOD ACT IN THE QUEEN'S BENCH.

IMPORTANT OPINIONS OF THE JUDGES.

On Wednesday Jan. 17, two appeals from the Justice of Derby, under the Sale of Food and Drugs Act of 1875, were heard before Mr. Justice Mellor and Mr. Justice Lush; but owing to the cases not being sufficiently explicit on certain points they were sent back to the magistrates to be re-stated. There was, however, a good deal of argument, from which our readers will learn how the judges view the Adulteration Act. There were two cases—Sandys *v.* Markham, and Sandys *v.* Clarke—the appellant being the inspector appointed to prevent the adulteration of food and drugs in Derby. The Court took the first case of Sandys *v.* Markham, stated by the magistrates, from which it appeared that on March 24, 1876, at the County Hall, Derby, an information was laid by the inspector against Emma Markham, charging her with unlawfully selling to him "to his prejudice, half a pound of an article of food, purporting to be mustard, but which article was not of the nature, substance, and quality of mustard, which was the article then demanded by him." The charge was framed under the Act of 1875. It was proved, and not disputed, that on the day in question, the inspector entered the shop and asked for half a pound of mustard, and the respondent weighed out and supplied to him from a mustard-tin, half a pound of what appeared to be mustard; but there was no label on the tin indicating the nature of the article sold. But on an analysis, it was found to be a compound of mustard, with about 35 per cent. of wheaten flour, turmeric, and cayenne pepper. It was submitted, that notwithstanding the admixture of these articles, the article sold was of the nature, substance, and quality of mustard, and that the inspector not having paid the price of pure mustard, had got what he asked for, and value for his money. There was no proof of what were the relative prices of the pure mustard and of the article sold. It was alleged by the respondent, and not disputed, that she had bought the article in the state in which she sold it; but it did not appear of whose manufacture the article was, or whence she obtained it. It appeared on the reading of two letters from Messrs Colman, the mustard manufacturers, in reply to the request of the magistrates (and which were taken as evidence), that in the course of their business, they make and supply to their customers a considerable variety of articles of the nature of mustard, some professing to be "pure mustards," and others "mustard condiments," produced mainly by the admixture of wheaten flour; and that some regard the pure mustard as nauseous, and consider the mustard condiments more palatable. The inspector contended—first, that though the article might be said to be of the nature of mustard, it could not be said, considering the large admixture of flour, turmeric, and cayenne pepper, to be of the nature, substance, and quality of mustard; and, secondly, as he asked for mustard, he was entitled to receive pure mustard; or, if not, he ought to be informed by a label that the article was mixed with some other ingredient; and, thirdly, that the fact of Messrs. Colman selling mustard condiments as distinct articles of commerce from pure mustard, showed that the label was necessary to protect the seller. The case concludes—"We being of opinion—firstly, that the article so sold was, though not pure mustard, at least an article of the nature, substance, and quality of mustard; secondly, that the thing was not to the prejudice of the purchaser; and, thirdly, that the respondent was exempt from the penal consequences under sub-section 1 of section 6, on the ground that the matters or ingredients were not injurious to health, and were required for the production or preparation of an article of commerce in a state fit for consumption—dismissed the information. If the Court should be of opinion that the article sold was of the nature, substance, and quality of mustard, or that it was not sold to the prejudice of the purchaser within the meaning of the Act of 1875; or that sub-section 1 of section 6 exempted the seller of such an article from the penalties imposed by that section, then our decision will stand; if otherwise, the Court will please ask us to re-hear the case."

Mr. Buck appeared for the appellant; and Mr. Firth appeared for Markham; and Mr. Wills, Q.C., for Clarke.

Mr. Buck having read the case,

Mr. Justice Lush observed that, as far as the case stated, the article sold here was neither the "pure mustard" nor the "mustard condiment" that Messrs. Colman speak of.

Mr. Buck: It is composed of 65 per cent. of mustard, with 35 per cent. of wheaten flour, turmeric, and cayenne pepper; and that proportioned to the half pound would be as three ounces of the mixture to five ounces of the pure mustard. In the case of Clarke the difference was that there was 75 per cent. of mustard and 25 per cent. of wheaten flour, turmeric, and cayenne pepper. The learned counsel then quoted the preambles of the Adulteration Acts of 1874 and 1875, showing that the Legislature desired that food and drugs should be sold in a pure and genuine condition. Section 6 of the Act of 1875 prohibited the sale of articles of food and drugs not of the proper nature, substance, and quality of the article demanded by the purchaser, and a penalty not exceeding 20*l.* was imposed for the offence. Then the following proviso came in: "An offence shall not be deemed to be committed under this section in the following cases; that is to say (1) Where any matter or ingredient not injurious to health has been added to the food or drug because the same is required for the production or preparation thereof as an article of commerce, in a state fit for carriage or consumption, and not fraudulently to increase the bulk, weight, or measure of the food or drug, or conceal the inferior quality thereof;" then sub-section 4: "Where the food is unavoidably mixed with some extraneous matter in the process of collection or preparation." This section is important. It says: "Provided that no person shall be guilty of any such offence as aforesaid in respect of the sale of an article of food or a drug mixed with any matter or ingredient not injurious to health, and not intended fraudulently to increase its bulk, weight, or measure, or conceal its inferior quality, if at the time of delivering such article or drug he shall supply to the person receiving the same a notice, by a label distinctly and legibly written or printed, on or with the article or drug, to the effect that the same is mixed." Then the 13th section enables certain officers (including the appellant) to obtain a sample to submit it to analysis; and section 24 says: "In any prosecution under this Act, where the fact of an article having been sold in a mixed state has been proved, if the defendant rely upon any exception or provision contained in this Act, it shall be incumbent on him to prove the same." Then section 25: "If the defendant prove to the satisfaction of the justices or Court that he had purchased the article in question as the same in nature, substance, and quality as that demanded of him by the prosecutor, and with a written warranty to that effect, that he had no reason to believe at the time when he sold it that the article was otherwise, and that he sold it in the same state as when he purchased it, he shall be discharged from the prosecution, but shall be liable to pay the costs incurred by the prosecutor, unless he shall have given due notice to him that he will rely on the above defence." Now, here it was not proved that the defendant had purchased the article in question as the same in nature, substance, and quality as that demanded by the prosecutor, and she had no written warranty, and she had no reason to believe that the article was otherwise.

Mr. Justice Lush: That is the case of buying with a written warranty.

Mr. Buck: She has to prove all these things to entitle her to the benefit of this section. If she had a warranty she could recover the penalties from the person who sold the goods to her; but in order to do that she must show that she sold the article in the same state in which she received it. There is no protection to the seller of a mixed article unless he affixes a label showing that he sells it as a mixed article.

Mr. Justice Lush: What does the third sub-section of section 6 mean, "where the food or drug is compounded as in this Act mentioned?"

Mr. Wills: It means nothing at all. The former part of the Act has been struck out probably, and it has been left in.

Mr. Justice Lush: That must be so.

Mr. Buck continued: This question of the adulteration of mustard has been already decided in the case of Pope *v.* Tearle (ninth volume of the Law Reports, Common Pleas, page 499). It is a decision on the 3rd section of the Act of 1874, and it shows that this admixture of mustard brings the persons under the penalties of the law. It was there held that "a person who had sold mustard admixed with flour and turmeric (substances not injurious to health), declaring at the time of such sale that he did not sell the article as pure mustard, had not been guilty of any offence, and that it was not necessary to declare the proportion of the substance admixed." If he had sold the article without such a declaration he would have been convicted of the offence of selling an article adulterated as unadulterated. The question in this case is whether this stuff sold to the appellant was of the "nature, substance, and quality of mustard."

Mr. Justice Lush: Is it to be alleged that flour is of the nature of mustard?

Mr. Justice Mellor: Would not it be the same as saying that milk and water are the same?

Mr. Buck: There was a case about gin, which I have not been able to find, where there was an admixture of 40 per cent. of water to 60 per cent. of gin, and it was held that that was not gin.

Mr. Justice Mellor: It was gin and water.

Mr. Justice Lush: At present I am utterly unable to see how flour can be of the same "nature, substance, and quality as mustard."

Mr. Justice Mellor: In the gin case did they hold that was an adulteration?

Mr. Buck: Oh, yes.

Mr. Justice Lush: That water was not of the nature of gin.

Mr. Buck: The next point is whether this was a sale to the prejudice of the purchaser."

Mr. Justice Mellor: It was not bought for consumption. The case does not state for what purpose it was bought.

Mr. Justice Lush: It has reference to the article that is sold to the public.

Mr. Buck: I put it thus: That a person by asking for mustard is entitled to be supplied with mustard, and not with sixty parts of mustard and forty parts of flour, turmeric, and cayenne pepper.

Mr. Justice Mellor: You say that it ought to be hot in the mouth, and they say it ought not. It might be required for a mustard-plaster.

Mr. Justice Lush: If the buyer asks for a pure article, and gets an adulterated article, that is to his prejudice, I suppose?

Mr. Buck: Yes.

Mr. Justice Lush: The 6th section says that the seller shall not be deemed to have committed an offence if the ingredients were necessarily put into the article sold to render it fit for carriage or consumption.

Mr. Wills: Have not the magistrates found it so?

Mr. Justice Lush: This admixture is liked by many people; but nobody would say that the admixture was necessary to make it "fit for carriage or consumption." It is perfectly fit for consumption when it is pure.

Mr. Firth, for the respondent Markham, began by reading from a copy of the *Times* of May 29 last, the decision of Baron Cleasby in the gin and water case referred to above. It was an appeal under the 6th section of the Adulteration Act of last year; and the question was whether, when a man asked for gin, it was an offence to sell him gin and water.

Mr. Justice Lush: The retailer is liable, whether he knows of the adulteration or not.

Mr. Justice Mellor: He is bound to know what the article is composed of that he is selling.

Mr. Justice Lush: It is only where he buys with a warranty that he is protected.

Mr. Firth: The gin case goes to this point—that a certain article was sold as gin containing 20 per cent. of water, and it was held to be no adulteration; and according to the finding here, the sale of the mustard would be 35 per cent. below proof.

Mr. Justice Lush: It does not appear that Mr. Colman sells his "mustard condiments" as "mustard."

Mr. Justice Mellor: In contracts of sale in products where there is a certain mixture of inferior matter, the question arises whether it reasonably answers the description. But the fact here is, that there is such a thing as mustard commonly sold which is pure; and there are also sold "mustard condiments." The magistrates have found the facts in such an odd way that it is difficult to decide. With regard to two of the questions I should have very little hesitation—viz., with regard to the article sold being of "the nature, substance, and quality of mustard, and not sold to the prejudice of the purchaser;" but then comes the difficulty in their finding—"or that sub-section 1 of section 6 exempted the seller of such an article from the penalties imposed by that section, then our decision will stand; if otherwise, the Court will please ask us to re-hear the case." I don't know what they mean by that.

Mr. Firth: They have found that the mustard was in a fit state for consumption. I submit that that was a finding within their jurisdiction.

Mr. Justice Lush: They do not negative the remaining part of the sub-section—"and not fraudulently to increase the bulk, weight, or measure of the food or drug, or conceal the inferior quality thereof."

Mr. Wills: I am quite sure that they would negative that if it were sent back.

Mr. Justice Lush: It may be that the mixture of a certain portion may be required, but that much more would be injurious.

Mr. Wills: I gather from the statement of the case that it never was suggested that there was anything fraudulent or improper.

Mr. Justice Mellor: One doesn't find any statement that it was necessary for the purpose of making it an article of commerce.

Mr. Wills: They have two letters of Messrs. Colman; and I have no doubt that the magistrates would to some extent act upon their own knowledge about such matters; and if it be, as is stated, that the majority of people prefer this admixture to the genuine mustard, then it is an article of commerce, and the mixture is necessary to reduce it to that state, so as to make it fit for consumption as an article of commerce.

Mr. Justice Mellor: It is ambiguous. But if their finding really is such as you suggest, then it would be found a good answer. I certainly don't see anything which induces me to think that it was put in to add to the weight for the purposes of fraud.

Mr. Wills: Of course if it was I quite agree with Mr. Justice Lush that that protection of sub-section 6 would be gone.

Mr. Justice Lush: As to the matter being sold to the "prejudice of the purchaser,"—suppose a man orders a pure article, and he does not get it pure, he is prejudiced.

Mr. Wills: But isn't the man bound to show that he expected to get pure mustard? Whether it is to prejudice or not is a question of fact in each case, and therefore the finding of the magistrates is conclusive.

Mr. Justice Mellor: The case had better go back.

Mr. Justice Lush: They ought to find whether this was the substance usually sold as mustard; and whether the public who order the mustard expect to get this compound instead of pure mustard. If so, then I shall say that the parties who get it are not prejudiced; and then, thirdly, if they don't find that in favour of the respondent, then that exemption of the first sub-section of section 6 does not apply.

The case was remitted back to the magistrates accordingly to re-state the case.—*The Grocer.*

Copper in French Preserved Peas.

At Marlborough Street Police Court on Monday, Louis Barron, Compton Street, Soho, importer of foreign provisions, was summoned before Mr. Knox, charged with selling French preserved peas in tins which were adulterated with copper and, consequently, injurious to health. There were three other dealers summoned, but it was arranged to take one case as decisive of the rest.—The Metropolitan Board of Works prosecuted.—Similar summonses were heard at this court about three weeks ago, and dismissed on technical grounds taken by Mr. Lewis. It was then arranged as differences between analysis results were shown to exist that a portion of the peas should be sent to Somerset House for the investigation of the government analyst.

Frederick Taylor, an officer of the Board of Works, proved purchasing a tin of French *petits pois* at the defendant's shop for analysis.

Mr. Charles Piesse, No. 303, Strand, analyst, analysed a portion of the peas, and produced some of the copper. He had no doubt that copper was present on the peas. He found the result of his analysis was to discover ·56 of a grain in a specified portion of the peas. This quantity taken regularly would, in his opinion, prove injurious to health.—The government certificate of analysis was produced. It stated that the quantity of copper specified contained ·31 parts of a grain. The analysis of Mr. Piesse showed ·56 parts of a grain.

Dr. Evans, district of London officer of health, thought that the quantity of copper found in the peas, if taken repeatedly, would be injurious to health.

Mr. E. Lewis, for the defence, said what he had to establish was that by no possibility could the quantity of copper, taking even the analysis of Mr. Piesse, prove injurious to health.

Dr. Pavy, F.R.S., No. 35, Grosvenor Street, author of a work on food, and lecturer at Guy's Hospital, was of opinion that ·31 of a grain of copper would not be injurious to health. If a tin of peas was consumed at once, he was of opinion that no injury to health would result. Copper was one of the natural constituents of the body.

Mr. Knox said the question was one of great public interest. On the one hand if he gave an adverse decision an important trade would be seriously affected; on the other, if the theory that the peas were injurious to health were correct, the public would be poisoned. It had been shown in the cross-examination for the defence how widely medical men differed in opinion. Taking into consideration the importance of the case he would adjourn his decision that he might fully consider the evidence, and he hoped that the result of the adjournment would be to induce qualified persons to discuss the question in medical circles, and to give him the benefit of their deliberations.—The summonses were then adjourned.—*Standard.*

Poisoning by Phosphorus Paste.

An inquest was held on Thursday, at Dalston, by Mr. Humphreys, concerning the death of Mrs. Emily Mary Ann La Riverie, aged 31 years. Since her last confinement, two years ago, she had suffered from nervous depression.

Mr. John Bambro, grocer, 47, Greenwood Road, recollected, on the 8th inst., selling a lady two threepenny bottles of phosphor paste, but he could not again recognize her. It was a very unusual occurrence for a person to ask for two bottles, but deceased said she was overwhelmed with beetles. The bottles were marked poison, and there was no law against them selling twenty bottles to one person.

Mr. Alfred Thomas Gibbons, surgeon, who was called in to deceased, said that she had swallowed phosphor paste two or three times previously. She said that she had committed the unpardoned sin and wished to die. She died on Sunday from exhaustion, consequent on poison by phosphor paste.

A consultation took place amongst the jury as to the legislature allowing poison to be sold in such a manner, which they strongly condemned. The Coroner concurred with these remarks.

A verdict of suicide whilst in a state of unsound mind was returned.—*Standard.*

Poisoning by Carbolic Acid.

On Wednesday, Mr. John Humphreys, the Coroner, held an inquiry in Finsbury, relative to the death of John Padian, aged 78, through swallowing a quantity of carbolic acid.

Sarah Padian, the widow of the deceased, a labourer, stated that on the night of Saturday, the 20th, they provided themselves with a bottle of beer for Sunday. About seven in the evening of Sunday he asked for some, and she accordingly poured out and made hot what she took to be beer, but which proved to be carbolic acid. Finding him to be in pain, she also took a small quantity to satisfy herself that such was the case, and called in a neighbour and a doctor, but deceased died two hours after.

The jury returned a verdict of "Death by misadventure."—*Echo.*

Death from Eating Hemlock.

An inquest respecting the death of Gabino Simone Carcich, 20 years of age, who died at the Sailors' Home, Falmouth, on Monday January 15, was held on Tuesday by Mr. Carlyon.—Francesco Moroto and Francesco B. Luigi Bosco, the deceased's comrades, gave evidence, the former stating that he partook of what he believed were similar herbs to those that caused the death of the deceased, but he felt no ill effects, nor did the deceased show any alarming symptoms until two hours after he had eaten the herb, when they had arrived at Falmouth, having rowed there from St. Just in Roseland.—Mr. Vigurs, surgeon, who was with the deceased up to the time of his death, gave it as his opinion that he ate the leaves of hemlock, the symptoms being similar to those of hemlock poisoning, and other deaths having occurred in the locality through persons having eaten of that herb.—The jury returned a verdict of "Death from poisoning."—*Western Morning News.*

Notes and Queries.

[532]. LIQUOR FERRI MAGNET. PHOS. COMP., or Lightfoot's Solution of Iron.—Can any reader inform me whether there is a published formula for this preparation, and, if so, where it is to be found?—F. J. B.

[533]. BOILED OIL AND GLYCERINE.—Can any one inform me how to mix Glycerine and Boiled Oil together and remain transparent?

H. S.

[534]. LAC SULPHURIS.—Could you favour me by inserting in your next issue the formula for Milk of Sulphur according to the Pharmacopœia of 1721?

SIRIUS.

"*Lac Sulphuris, P.L.* (1721).

℞ Sulphuris partem unam.
Calcis vivae, vel Salis Tartari partes tres.

Coque in Aquæ Fontanæ q. s. ad solutionem Sulphuris. Filtra calidè; praecipita cum Spiritu Vitrioli; edulcora, et sicca."

[535]. COCCULUS INDICUS.—I shall feel extremely obliged if any reader will inform me through the Journal regarding the dose of Cocculus Indicus. It is being used by some medical men in London, but I can ascertain nothing definite as to the strength of the tincture used by them. What proportion, for instance, might be used with safety to make a tincture—dose 10 to 30 minims? Also whether with Proof Spt. or S. V. Rect?

"SCOTUS."

[536]. SYR. FERRI ACETATIS c. STRYCHNIA ET QUINA.—R. G. would be obliged by being supplied with a form for making this preparation.

Obituary.

Notice has been received of the deaths of the following:—

On the 4th of December, 1876, Mr. George Braylesford Greaves, Chemist and Druggist, Clifton, Derby. Aged 72 years.

On the 9th of January, 1877, Mr. G. T. Naldrett, Pharmaceutical Chemist, late of Hammersmith and Bognor. Aged 34 years. Mr. Naldrett had been a Member of the Pharmaceutical Society since 1872.

On the 15th of January, 1877, Mr. Albinus Roberts, Pharmaceutical Chemist, St. Albans. Aged 63 years. Mr. Roberts was one of the Founders of the Pharmaceutical Society and a Subscriber to the Benevolent Fund from its commencement.

On the 15th of January, 1877, Mr. Joseph Carr, Chemist and Druggist, Normanton.

On the 16th of January, 1877, Mr. William Willson, Chemist and Druggist, Alford, Lincolnshire. Aged 69 years. Mr. Willson had been in business at Alford nearly fifty years.

Correspondence.

THE MILK OF SULPHUR QUESTION.

Sir,—Mr. Symons, of Barnstaple, has written a letter which requires correction, and one dealing in personalities so great as to display his animus in no common form. A little calculation would have shown him how absurd it is to talk about a hogshead of water as the quantity required to "clean" one pound of selenited lac sulphuris. His enthusiasm has carried his imagination out of the sphere of lac sulphuris altogether.

My stand-point is this: if properly prepared, milk of sulphur should be free from calcium sulphate whether prepared by the old London form or the Edinburgh one, and it matters not how much water it required to dissolve the selenite, perfect freedom from it is proved by the fact of the lac sulphuris, when submitted to sublimation, leaving no residue.

Want of proper washing is the cause even now of the adulteration coupled with the use of sulphuric acid. I affirm that the test given more than a hundred years ago is the same as recommended by Professor Redwood in Gray's 'Supplement,' *i.e.*, sublimation, and therefore, the Edinburgh and old London formulæ, when the instructions were adhered to, yielded a pure sulphur, and not the adulterated rubbish, containing 50 or 60 per cent. of plaster of paris, advocated by Mr. Symons and others who think as he does.

Does Mr. Symons think that calcium sulphate is easily sublimed? If he does, we shall leave him to indulge in his belief, and think of him as one hopelessly beyond conviction.

As regards Professor Redwood, I must say his evidence requires some explanation, and I cannot reconcile his altered views.

In Gray's 'Supplement,' 3 Ed. 1857, pp. 948 and 949, are given three formulæ for the preparation of precipitated sulphur, viz., a Continental, a United States and a descriptive British one, that of Ph. London. 1851. All are to be prepared by the hydrochloric acid process.

Now I defy Mr. Symons, and all the chemists and druggists in Great Britain, with Professor Redwood and Mr. Oliver Pemberton in conclave, to prove that sulphate of lime should form an integral admixture with the sulphur precipitated by those processes. The thing is impossible. But what is more, Professor Redwood, on p. 949, says the synonym of precipitated sulphur is "lac sulphuris."

Surely in the face of such facts, and with the authorities quoted in my former letter, not one leg is left whereon Mr. Symons and his fellow partisans can stand.

Why Professor Redwood has changed his way of thinking I know not; but I say, as the responsible Editor of the 'British Pharmacopœia,' the medical profession, as well as the public at large, have a right to demand some explanation from his hand not only as to his change of "front" but why the words "lac sulphuris" or "milk of sulphur" were not inserted in the B. P., 1867.

Some good reason was the cause of the omission, no doubt. What was it, and why? If Professor Redwood is right now, he was wrong in 1857.

Mr. Symons should know that selenite is crystallized calcium sulphate, and not ask to be instructed on such a point.

Mr. Pemberton's evidence may satisfy Mr. Symons and others; I have no desire to dispute their tastes, any more than I have the inclination to attach myself to erroneous views.

How can calcium sulphate be a beneficial admixture?

Why not mix jalap and scammony with calcium sulphate if it possesses such beneficial effects?

All authors, then, are agreed that lac sulphuris and precipitated sulphur are one and the same thing, and this was Professor Redwood's opinion in 1857. Mr. Symons' expression about "half-instructed analysts" is ungracious and ungentlemanly.

The Runcorn magistrates were perfectly right in the decision arrived at. A decision otherwise would have been against facts and figures.

HENRY BROWN.

Northallerton, Jan. 20, 1877.

Sir,—From time to time the formulæ and the nomenclature of the pharmacopœial preparations have been again and again altered, the former with the object of improving their medicinal efficacy, the latter with the purpose of more exactly or more clearly indicating their composition. These latter have sometimes been such that if vested in their newest garb their inventors would hardly recognize them. Thus, "Balsamum Traumaticum," of 1746, in course of time became "Tr. Benzoini Co." "Mercurius Dulcis Præcipitatus," of 1721, "Hydrargyri Chloridum," and "Lapis Infernalis sive Septicus," of 1721, became "Potassæ Hydras." or "Potassa Caustica." "Lac Sulphuris," of 1721, though not so completely metamorphosed, is changed to "Sulphur Præcipitatum," a name which it has retained to the present day. Not only was its nomenclature improved but an improved formula was prescribed for its preparation. As when sulphuric acid was employed in its manufacture the resultant precipitate contained some 50 per cent. of calcium sulphate, which no amount of "diligent washings," with an unlimited number of "parcels of water," could well get rid of, hydrochloric acid was substituted for it. Here, in passing I would observe that the London formula, as quoted by Mr. H. Brown, only directs the precipitate to be washed "in fresh parcels of water," till it becomes insipid. That certainly could not mean till all the calcium sulphate was got rid of, for that has less taste than the sulphur. It doubtless meant until every trace of acid had disappeared. The improved formula was evidently intended to prevent the possibility of a person desiring to take a dose of sulphur introducing at the same time into his stomach at least as large a quantity of inert, if not noxious, sulphate of lime. It was not meant to be an addition to the materia medica, the intention was to substitute a scientifically-prepared remedy, for one unscientifically prepared—when the one appeared the other was struck out. Sulphate of lime is not an article of any materia medica. I never heard of any one pretending that it possesses therapeutic virtues, but if what Mr. Pemberton says (page 584) be true then sulphate of lime should forthwith be added to our materia medica, in order to be mixed with any and every purgative powder, to ameliorate its action, and "soften the motion to a creamy consistency that has to come away without pain to the patient." But I don't think Mr. Pemberton will immortalize himself by bringing it into vogue.

I hold that to adulterate pepper with ground rice is excusable compared with adulterating sulphur with sulphate of lime. What would a druggist think if a grocer were found selling arrowroot mixed with sulphate of lime? Yet the fraud would be no greater than the other, beyond the fact that the consumer of the arrowroot would be likely to swallow more of the deleterious adulteration than the consumer of the sulph. præcip.

I deny emphatically that there is either a "great or continuous demand for the genuine (save the mark!) old milk of sulphur," and assert most positively that the reverse is the case. It were sad indeed if in these days of growing enlightenment it were not so. I can only infer from Mr. Symons' statement that the people of Barnstaple who patronize physic are exceptionally benighted. It is many years since I kept any other than the pure article, and when I kept both I never in my life met with an individual, rich or poor, literate or illiterate, who preferred *per se* the sophisticated article to the pure one. Occasionally if a customer were asked whether he wished that at 1*d.* or that 1½*d.*, he would say that he was accustomed to buy that at 1*d.*, but whenever time would permit the explanation, that the one was impure and the other pure, and half the dose would suffice forty-nine times out of fifty, the latter would be preferred, and I have never once found the impure article required since I determined to have none of it. Dr. Bell (*The Analyst*, p. 581) states that out of nine samples sold as "milk of sulphur," eight were genuine, "genuine" in an antithetical sense to that employed by Mr. Symons, *i.e.*, containing no calcium sulphate, thus corroborating my assertion that the reverse of Mr. Symons' statement is correct.

As Sir Robert Peel, when addressing the House of Commons, said of Lord Palmerston, "we are all proud of him," so I am sure every pharmaceutical chemist and member of the Society will say of Professor Redwood; and because they have such regard for him, it is a matter of regret to numbers that he should give his aid to the side he does in this question. The Pharmaceutical Society should be like Cæsar's wife—above suspicion. The desire and endeavour to discountenance anything and everything savouring of adulteration should be unmistakable and patent. In opposition to what Mr. Pemberton and Professor Redwood stated at Runcorn Petty Sessions, I venture to say that a prescription taken to any first-class dispensing pharmacy, either metropolitan or provincial, containing "lac sulphuris," would almost certainly be dispensed with pure precipitated sulphur. In nineteen cases out of twenty the adulterated article would not be found on the premises. The difficulty of mixing the pure article with water may be a little greater than that of mixing the impure, but it is scarcely greater than every cook has to encounter in mixing flour and water to make melted butter, or any poor ignorant person in making a dish of "hasty pudding." Lastly I would point out, how fallacious is the argument that "lac sulphuris" specially indicates "sulphur containing sulphate of lime." In the Pharmacopœia of 1721, the earliest record we have of its being an officinal preparation, two forms are given for its manufacture—the result of following one is to make an impure precipitated sulphur, of the other to produce a pure precipitated sulphur, but both were called "lac sulphuris."

I have just received a circular from the Chemists and Druggists' Trade Association, soliciting me to become a member, but while its funds are spent in defending these milk of sulphur cases I hardly feel disposed to do so. I observe that in the case the Association defended, it was admitted that the article was dispensed unlabelled.

ROBT. CHIPPERFIELD.

Southampton, Jan. 23, 1877.

T. B. writes that he considers "Mr. Crow's translation of a quotation from the P. L., 1851, is very creditable, one little inaccuracy excepted. The words "Milk of Sulphur" are not in the original." T. B. does not appear to have read the note to the same effect appended to Mr. Crow's letter.

TRACINGS OF AUTOGRAPH PRESCRIPTIONS.

Sir,—Having recently had the pleasure of reading through the books of autograph prescriptions in the library of the Pharmaceutical Society, I conceived the idea of possessing a collection of my own, but as real autographs prescriptions are quite out of the reach of most assistants, I am obliged to content myself with the next best thing, viz., copies, which for purposes of study are of equal value. I cut up a sheet of architects' tracing paper into pieces the size of a half sheet of note paper, and laying one of these over the prescription to be copied, I very carefully traced every line, with ordinary ink and pen, and afterward mounted them in an ordinary 1*s.* scrap book; and I now have a very nice collection. A prescription after a little practice, may be copied in a little over five minutes. I merely throw this out for the benefit of my fellow assistants, to whom it may be new. I observe that most of the "lithographed" prescriptions are mere tracings.

ASSISTANT.

THE MICROSCOPIC STRUCTURE OF THE STEM OF JABORANDI.

(*Pilocarpus Species.*)

BY M. H. STILES.

Few drugs of recent introduction have received the amount of attention accorded to that which is the subject of this paper: yet, although much has been written respecting its botanical origin, chemical composition, and physiological action, I believed no account of its microscopical structure has been published, with the exception of a slight outline given by Professor Planchon in the *Journal de Pharmacie et de Chime* (1875, vol. xxi., p. 295).

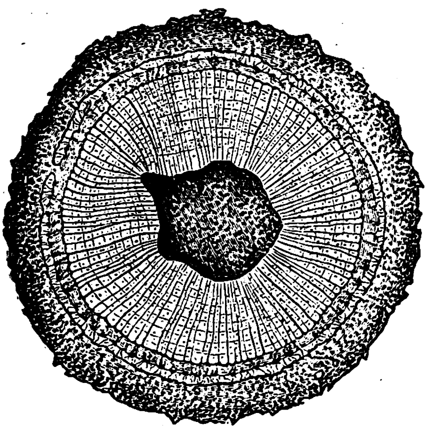

Fig. 1. Section of stem of Jaborandi (*Pilocarpus species*). Magnified 10 diameters.

Fig. 1 exhibits a transverse section of a stem, about ⅜ of an inch in diameter, taken from the upper portion of an internode, and will give a good general idea of the distribution of the various tissues. The pith has an irregular pentangular outline, one of the angles being especially prominent, this angle being that which is nearest to the base of a leafstalk, or the triangular scar remaining after the decay of the petiole. If a section of a young stem be made exactly across a node the pointed portion is found to be prolonged into the leafstalk, carrying with it bundles of spiral vessels and entirely dividing the zone of woody tissue; the latter comprises about three-eighths of the semi-diameter of the stem, it is traversed by very fine medullary rays, and contains numerous small vessels. A little beyond the wood zone is seen a ring of tissue which will afterwards call for special remark; outside this is the bark parenchyma, presenting near its exterior a number of oval glandular cavities and bounded by several layers of dark-coloured cork cells. The outer edge of the bark is somewhat rugged, partly due to contraction and consequent disruption of the tissue during drying. There were no hairs present on the specimen examined, and the epidermis had nearly disappeared, being only occasionally present in small patches.

The bark so readily separates from the wood, especially in a young stem, that considerable care is required in order to obtain and mount a characteristic section.

In more minutely describing the component portions of the stem I will begin with the medulla. The irregular form of this is well shown in fig. 1. In a moderate sized stem it occupies about one-fourth of the diameter. The cells of which it is composed are cylindrical in form and arranged more or less in vertical columns with tolerably large interspaces, their length in the central portion of the pith being about equal to their diameter, but towards the outer part they become narrower and longer. The cell-wall is slightly thickened by secondary deposit and irregularly pitted, the pits being oval or oblong and arranged with their longer diameter at right angles to the axis of growth.

Many of the cells contain a yellow or yellowish brown colouring matter, and nearly all contain starch; the granules, which frequently occur in groups of two, three or four, varying in size from ·00008 to ·0004 inch in diameter; the simple ones are regular in shape, being uniformly round, with a central nucleus, and without striæ; examined by polarized light they are seen to be highly doubly refractive, the usual black cross being very distinct and regular.

Besides starch, the cells of the medulla contain an abundance of raphides. These, which proved to be oxalate of calcium, are met with in two forms:—rhomboidal crystals, one, sometimes two, in a cell, and spherical clusters, the latter occurring much less frequently than the former. The cells containing raphides are generally free from starch. There are also present, in addition to starch and raphides, bodies which externally bear considerable resemblance to very large granules of the former, but differ in not being affected by polarized light or by solution of iodine.

Closely investing the medulla, and forming an irregular cylinder projecting more or less into it, lies that portion of the primary wood to which the term medullary sheath has been given. This tissue consists chiefly, in the present case, of two to three or even four rows (the largest number occurring near the prominently pointed portion of the medulla previously mentioned) of spiral vessels, interspersed with long pitted woody fibres and occasionally reticulated vessels. The spiral fibre is a single one and is coiled in the normal direction, *i. e.*, from right to left when looked at from above.

The medullary rays are very numerous and well marked; as seen in a transverse section, they are composed of from one to three or sometimes four rows of cells, elongated radially and minutely pitted; they contain starch granules, usually simple and much smaller than those found in the cells of the medulla; crystals are not present in the rays traversing the wood.

The woody tissue, which in the stem figured occupied nearly half the semi-diameter, is exceedingly dense, the cells being so consolidated by secondary deposit that but a small cavity is left; the walls are not pitted. Woody parenchyma, distinguished by its thin-walled slightly pitted elongated cells with square or rounded ends, occurs rather frequently in combination with the vessels; the latter which are slightly oval in transverse section are numerous but small, the longer diameter of the largest being not more than ·0015 inches: they have slightly oblique septa with circular perforations and are profusely pitted with very minute oval bordered pits arranged in a somewhat spiral manner. The woody tissue is divided into irregular zones varying much in width, but generally narrow, by the occurrence at intervals of one, two, or sometimes three, rows of thinner-walled wood cells, frequently containing starch.

The cambium tissue is interesting; it consists of several layers of exceedingly thin-walled cells, showing in transverse section a quadrangular outline, elongated tagentially (D, fig 2). In radial section they are seen to

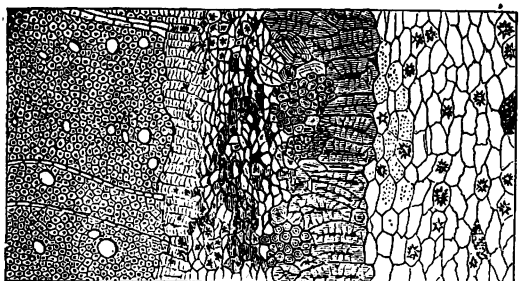

Fig. 2. Section of portion of stem of Jaborandi (*Pilocarpus species*).—A, Mesophlœum; B, Sclerenchymatous zone; C, Liber bundles; D, Cambium; E, Woody tissue. Magnified 100 diameters.

be of two forms;—those in continuation with the medullary rays being of a similar type, and containing comparatively large conglomerate raphides of oxalate of lime or minute starch granules; the others being of the prosenchymatous type, long and tapering at both ends, also containing conglomerate raphides, much smaller than those just mentioned. In some of these tapering cells from twenty to thirty minute crystals might be counted, diminishing in size to accommodate themselves to the internal form of the cell. In transverse section the raphides of the prosenchymatous cells are not often seen, being washed out in the usual preparation for examination, while those of the cells of the medullary rays of the inner liber are readily retained. The cells of the inner liber exhibit in transverse section a somewhat peculiar appearance, their walls being wrinkled and irregularly thickened; the author has observed this in the corresponding tissues of other stems, and believes it may be due to a collapse of the cell walls, caused by the active growth of the wood on the inside and the resistance of the schlerenchymatous zone without; followed, possibly, by a cementation of the cell-walls thus placed in juxta-position. This thickening by no means takes place uniformly; cells frequently occurring in which little or no change appears.

Outside this tissue, and partly within and partly mixed up with the ring of thick-walled cells, are isolated bundles of liber tissue, at least they appear isolated in transverse section, though a tangential one shows that they anastomose with each other, forming a rough network through the meshes of which pass continuations of the medullary rays.

These liber cells are long and tapering, thick-walled and roughly hexagonal in transverse section; long and beautifully pitted, bast vessels are also occasionally met with.

Just beyond the liber tissue occurs one of the most characteristic features of the stem—an almost perfect zone of from one to two rows of very beautiful sclerenchymatous cells, for the most part, as will be seen from the engraving (B, fig. 2), elongated radially. In these intra-cellular deposition has taken place to such an extent that in many cases the original cavity has been almost filled up; the successive layers of deposit may be rendered very evident by treatment with diluted sulphuric acid (1 part to 3 of water). The porous canals, simple and branched, with which these cells are freely traversed are strikingly shown by deeply staining a section with magenta, then quickly washing it with spirit, oil of cajeput, and turpentine successively, and mounting it in cold balsam; treated in this manner the canaliculi are seen to be injected, as it were, with the staining fluid, the thick cell-wall being not at all, or only slightly, coloured. Cell contents are rarely found in the older cells; in the younger ones a granular substance, staining deeply with magenta, is sometimes met with. The individual cells of this tissue, isolated by Schultze's method of maceration, present the most varied and peculiar shapes. The presence of this thick-walled and unyielding zone of cells will, to a great extent, account for the invariable separation of the bark from the wood during drying.

The mesophlœum occupies about one-fifth of the semi-diameter of the stem, and presents several interesting features; the cells of which it is composed are thin-walled, moderately large, irregular in form, and usually elongated tangentially. Sclerenchymatous cells are occasionally present, either isolated or in small groups. Of the cell-contents of this portion of the stem probably the most conspicious, especially near the tissue last described, are large sphæraphides of oxalate of calcium. It is a noteworthy fact that only this form of crystal is found in the bark, whereas both varieties are met with in the medulla, though in the latter the rhomboidal greatly predominates. Starch is also abundant, the granules being rather smaller and less frequently aggregated than those present in the cells of the medulla. Scattered over the whole of the mesophlœum, but becoming more abundant near the epiphlœum, are cells containing a dark brown resinoid substance, partially soluble in solution of potash, and acquiring a greenish-black colour with perchloride of iron. When a longitudinal section is examined it is found that these cells are invariably arranged in long vertical columns.

Near the epiphlœum occur large oval interspaces, with the longer diameter arranged tangentially in transverse, and longitudinally in radial sections; these are evidently the remains of old oil glands, with which the bark of a young stem is plentifully dotted. The bordering cells of these cavities are usually somewhat ruptured, and those immediately surrounding them contain the dark brown resinous deposit recently alluded to. The epiphlœum consists of six or seven rows of deep brown tabular cork cells, elongated tangentially, with the remains of the ruptured epidermis on the exterior.

Not desiring to confine myself to the examination of one stem, I obtained samples from various sources with the view of comparing their structure, and among these was an authenticated piece of a young stem of *Pilocarpus pennatifolius*, from Kew, kindly furnished by Mr. Holmes.

Some of these, including that from Kew, were found to differ to a certain extent from the stem described, both in their internal structure and external characters, the most prominent variations being the following:—the occurrence of an intercellular substance in the woody tissue, about one-third of the distance from the cambium to the medulla, forming an interrupted zone, sometimes single, sometimes double. A portion of this tissue is shown in Fig. 3. The stem from Kew being a young one, this zone in it was not perfect, and was nearer the cambium. It was at first thought to be a resinous deposit, but the application of various reagents dissipated this idea. In transverse section it occurs in irregular patches, the outline of which is determined by the walls of the cells with which it is in contact; in vertical section the deposit forms columns of considerable length. It is of a pale yellow colour, and perfectly translucent, so

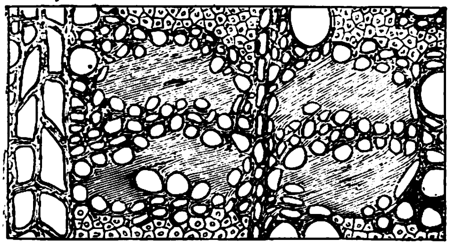

Fig. 3. Section of portion of stem of Jaborandi, probably. *Pilocarpus pennatifolius*; showing inter-cellular deposit. Magnified 175 diameters.

much so that when a bleached section is mounted in balsam or dammar this portion of the stem is nearly as transparent as the medium in which it is placed. The walls of the cells which border upon it can be readily distinguished. It was found to be insoluble in the following:—benzine, ether, alcohol (boiling), oil of turpentine (boiling), chloroform and hot solution of potash. It is slightly coloured by magenta; heated in strong sulphuric acid it darkens much more rapidly than the adjoining woody tissue. It is usually homogeneous in structure, though occasionally fissures may be detected. Touched with the point of a needle it is found to be tough and moderately hard. When a transverse section is boiled for two or three minutes in a mixture of one drachm of dilute nitric acid and two grains of chlorate of potash (Schultze's process) this deposit becomes dark and opaque, and after isolation from the neighbouring bleached and disintegrated cells has, under a high power, a decidedly spongy appearance.

I have not been able to satisfactorily determine the nature of this tissue, if it can be so termed. Judging from the foregoing experiments it may possibly be a modified form of cellulose infiltered by some substance not soluble in ordinary reagents but oxidized and removed by the nitric acid treatment. In the young stem from Kew, this substance is readily stained by carmine, the surrounding woody tissue not being affected; the same colouring agent applied to the older foreign stems gave no result. In the root of the latter it is much more abundant than in the stem, but whether this rule holds good in the Kew-grown plant I am unable to say, nor have I had an opportunity of examining the root of the stem first described and figured.

Both Planchon and Hardy agree in considering this a resinous deposit, but the negative results obtained with the usual resin solvents will I think disprove their statement.

The presence of this deposit in some stems and its absence in others, coupled with the fact that those containing it have usually a lighter, thinner, and more easily separable bark, would seem to give additional confirmation to the fact, already noticed by other observers, that there are two if not three varieties of *Pilocarpus* met with in commerce under the name of Jaborandi, and that one of these so closely corresponds with an authenticated specimen of *Pilocarpus pennatifolius*, both in internal structure and external characters, as to justify its being referred to that species.

Before however pronouncing decidedly on this point it would be well to examine the stem of a more mature authenticated specimen than that I had at my disposal, and I hope that I may be in a position to do this. The subject is one of great interest and deserves fuller investigation.

300, *High Holborn.*

BROMIDE OF ETHYL AS AN ANÆSTHETIC.

BY M. RABUTEAU.

At a recent meeting of the Academy of Sciences* M. Rabuteau gave some details of an investigation of the physiological properties and mode of elimination of bromide of ethyl.

Bromide of ethyl (C_2H_5Br), or "hydrobromic ether," is a colourless liquid, with an agreeable odour; it boils at about 40° C., has a density of 1·43, and burns with difficulty. The boiling point and density are therefore intermediate between those of chloroform and sulphuric ether.

Bromide of ethyl absorbed by the respiratory passages produces absolute anæsthesia as rapidly, or even more rapidly, than chloroform. This result has been established with frogs, rabbits, dogs, etc. After five minutes', sometimes after two minutes' inhalation, by means of a sponge saturated in bromide of ethyl, dogs are completely anæsthetized. The animals recover more rapidly than when chloroform is used.

When a solution of hydrochlorate of narceia or hydrochlorate of morphia was injected under the skin of dogs, before inducing anæsthesia, an action was observed analogous but perhaps inferior to the simultaneous action of narceia, or morphia, and chloroform.

Bromide of ethyl is not caustic, nor even irritant, compared to chloroform. It can be ingested without difficulty, and applied without danger, not only subcutaneously, but to the external auditory meatus and to the mucous membrane. In this respect it is preferable to chloroform, which is very caustic, and to sulphuric ether of which the ingestion is nearly impossible. Introduced into the human stomach in doses of 1 to 2 grams, bromide of ethyl does not produce anæsthesia as when absorbed in sufficient quantity by the respiratory passages. It soothes pain and does not disturb the appetite.

This anæsthetic is nearly insoluble in water. Nevertheless water shaken with it acquires a pleasant taste and odour. Frogs placed in water so saturated undergo anæsthesia in ten or fifteen minutes.

Bromide of ethyl is eliminated nearly entirely, if not completely, by the respiratory passages, whatever may have been the mode of absorption. At most only traces of it are found in the urine when it has been introduced into the stomach, and an extremely small quantity can be detected in that liquid when it has been inhaled. The author finds that bromide of ethyl does not decompose in the organism to form an alkaline bromide, such as bromide of sodium, a salt that is easily eliminated by the renal passages.

From his experiments the author concludes that bromide of ethyl is an anæsthetic agent possessing properties intermediate between those of chloroform, bromoform, and ether.

HOW TO KEEP VEGETABLE DRUGS.*

BY HANS M. WILDER.

Judging from several remarks the author has met with in various journals, a notion seems to prevail that vegetable drugs, particularly herbs and roots, cannot be kept except they are as much as possible hermetically sealed, or at least packed in tin cans, or saltmouths with tight-fitting covers; one person even goes so far as to seal the cover with beeswax every time the can has been opened, on the plea that drugs spoil by exposure to the air—*and still they spoil.*

This is in direct contrast with the assertion of old druggists, that in *their* youth herbs, etc., kept very well, although no better receptacles were at hand than drawers, boxes, paper bags, specie jars, etc. Furthermore, the wholesale dealers' stocks of herbs, etc., are generally in a fair condition, although kept in barrels, wooden bins, and boxes, and in a room where there is a constant draught of fresh air.

This latter condition solves the mystery! Vegetable drugs (and their powders) will not keep for a reasonable length of time except where the air in immediate contact with them can equilibrate itself, as it were, with the surrounding air; this, with exclusion of light and of extra moisture from a damp locality, are the three chief conditions necessary.

The reason of drugs spoiling, notwithstanding all extra care in the shape of tight fitting covers and the use of tins and glass, is the following:—

When herbs, etc, are properly dried, they still contain a not inconsiderable quantity of water, and will, if kept in non-porous receptacles, by each rise of temperature load the air on top with vapour which condenses at a lower temperature, and shortly the contents begin to grow mouldy. If, on the contrary, kept in porous receptacles, such as wood, pasteboard, etc., the moist upper layer of the air will equalize itself through the pores with the surrounding air. Herbs that are over-dried attract moisture as soon as the receptacle is opened. That vegetable drugs should be kept in a dry place it is not necessary expressly to state.

The foregoing is supported by the following experiments with vegetable powders, taken from *J. de Pharm. et de Chim.*, quoted in Buchner's *Repert. f. Pharm.* Hérouard (1862) found that most powders kept better in paper bags than in glass, and he instances a sample of powdered cantharides which was twelve years old and still gave an excellent blister, although kept all the time in paper; while a sample kept a year in close stoppered glass had become mouldy and quite lost its power.

Breau (1865) divides powders into three classes:—

I. Those that keep *only* in paper or pasteboard:—Aconite, angelica, belladonna, cantharides, conium, cochineal, columbo, digitalis, elecampane, hellebore, gentian, gum arabic, hyoscyamus, ipecacuanha, jalap, liquorice root, marshmallow, orris root, rhatany, roses, savin, stramonium, and similar powders.

II. Powders which keep as well in paper as in glass:—Agaric, angustura, arnica, anise, benzoe, cascarilla, catechu, charcoal, colocynth, cream of tartar, euphorbium, male fern, guaiac, ginger, Peruvian bark, rhubarb, saunders, tartar emetic, turmeric, etc.

III. Powders which keep only in well-stoppered bottles:—Asafœtida, camphor, castoreum, cubebs, gum tragacanth, opium, squills, etc.

The writer must add that tartaric acid keeps better in paper than in glass.

By conforming to the following, one's stock of vegetable goods will always be in a satisfactory condition. As soon as the first warm days come in spring, or in the forepart of summer, give all your herbs, etc., including the drawers, boxes, etc., a thorough airing and sunning. The sun, if not a scorching noon-day sun, will not hurt them. Do not put the herbs, etc., in tin cans or glass before they have cooled down a little; with drawers and boxes it makes no difference. Before setting them away garble and free them from the finest dust. If you have tins and glass, make one or two holes in the tin covers with a nail; with glass put a strip of pasteboard or a bit of thin stick of wood, or wire, between the stopper and the neck; the contents will be all the better for it. When you get your stock filled up from the wholesale druggist, open the parcels and give them a good drying before putting them away. When you dry the roots give them a good overhauling with an old clothes brush, so as to remove all the dust; roots are not hurt by a good heat. If possible, repeat this airing in the fall. As to powders, give them an airing at least once a year; and, before you put those you get from the wholesale druggist away, open the parcels and spread the powders in quite a thin layer to air-dry them. It is evident that the foregoing general rules do not apply to special cases; delicately coloured flowers and strongly scented herbs and roots must be treated carefully—dried in a shady place, and so on.

This seems troublesome, but is nothing more than is done every year in Germany and adjacent countries.

* From *The Druggists' Circular and Chemical Gazette*, January, 1877.

A COMBAT WITH AN INFECTIVE ATMOSPHERE.*

BY JOHN TYNDALL, F.R.S.,

Professor of Natural Philosophy.

A year ago I had the honour of bringing before the members of the Royal Institution some account of an investigation in which an attempt was made to show that the power of atmospheric air to develop life in organic infusions—infusions, for instance, extracted from meat or vegetables—and its powers to scatter light went hand in hand. I then endeavoured to show you that atmospheric air, when left to itself, exercised a power of self-purification; that the dust and floating matter that we ordinarily see in it disappeared when the air was left perfectly tranquil; and that when the air had thus purified itself, the power of scattering light and the power of generating life disappeared together. For the sake of reminding you of this matter, we will now cause a beam of the lamp to pass through the air. You see the track of the beam vividly in the air. You know that the visibility of the track is not due to the air itself. If the floating matter were removed from the air, you would not be able to track the beam through the room at all. You see the track in consequence of the floating dust suspended in the air. If the air be enclosed in a place free from agitation the dust subsides, and then as I endeavoured to show you a year ago, the air possesses no power of generating life in organic infusions. The nature of the argument is this. You see the dust as plainly as if it were placed upon your hand and you could feel it with your fingers. You found that the dust, when it sowed itself in organic infusions, produced a definite crop in those infusions; and you are equally justified in inferring that the crop thus produced is due to the germs in the dust, as a gardener would be in believing that a certain crop is produced from the seeds which he sows. I say that the inference that his crop is the product of the seeds that he sows is not more certain than the inference that those crops produced in the organic infusions are due to the seeds contained in them.

You know the method that we resorted to for the purpose of enabling us to get rid of this dust. The object was to allow the air to purify itself and it was done in this way. I have here the first chamber that was used in these experiments. You see at the bottom a series of test-tubes entering the chamber: they are air-tight, and

* A lecture delivered at the Royal Institution, on Friday, January 19, 1877. Reprinted from the *British Medical Journal*, January 27.

they open into it. There are windows at the sides, and here is a pipette through which the liquids can be introduced. Behind we have a door which opens upon its hinges. Now, imagine this perfectly closed; imagine it abandoned entirely to itself, left perfectly quiet. In a few days the floating dust of the air contained in the chamber entirely disappears: it has removed itself by its own subsidence; and then when you send a beam of light such as we have here through these windows, you see no track of the beam within the chamber. When the air is in this condition, you pour through this pipette infusions of beef, mutton, or vegetables into these tubes, and allow them to be acted upon by the air. Last year, between fifty and sixty of these chambers were constructed, and the invariable result was that these infusions never putrefied, never showed any change, were perfectly sweet months after they were placed there, as long as the air had this floating matter removed. You had nothing to do but to open the back door and allow the dust-laden air to enter the chamber to cause these infusions to fall into a state of putrefaction, and swarm with microscopic life, in three days after opening the door. I have a smaller chamber here—for we use chambers of different sizes—and it will enable you to understand our exact process. You see here the stand on which the chamber rests. There are two bent tubes that communicate with the outer atmosphere, for I wish to have a free communication between the air outside and the air within. You see the pipette through which the tube is filled. When the infusion is poured in, you place it in an oil-bath contained in a copper vessel, such as we have here, in which you boil it for five minutes. Now, that boiling for five minutes was found capable of sterilizing every germ contained in the infusions placed in these chambers. This year our experiments began by a continuation of those that we made last year. In order to enable you to judge of the severity of the results obtained last year, I have here five cases belonging to the experiments then made. You will see that the infusions are vastly concentrated because of their slow evaporation. The quantity of liquid is reduced to one-fifth of its primitive volume, but this one-fifth is as clear as rock crystal; whereas, the tubes exposed to the ordinary air outside fell long ago into utter putrefaction. They became turbid and covered with scum; and when you examine these infusions to ascertain the cause of that turbidity, you find it to be produced by swarms of small active organisms.

This year our inquiries began in the month of September. But we will pass over these inquiries for the moment and go to those of October. On October 29th, two members of the Royal Institution collected a quantity of fungi in Heathfield Park, Sussex. These were brought to London on the 30th. They were placed for three hours in warm water, and whatever juices they possessed were thus extracted from them. They were placed in chambers and digested separately. There were three kinds of fungi: we will call them red, yellow, and black. Now, I confess that, thinking I had secured a perfect freedom from any invasion of those contaminating organisms that produce putrefaction, I expected that we should find that these infusions of fungus would maintain themselves perfectly clear. To my surprise, in three days the whole of them broke down; they became turbid, and covered by a peculiar fatty, deeply indented, corrugated scum. Well, that was a result not expected, but I pursued the matter further. I got another supply of fungi. Even in this first experiment, I had adopted care at least as great as that which I adopted last year, and which led to a perfect immunity from the invasion of putrefaction. With the fresh supply of fungi, I operated with still more scrupulous care. The infusions were placed as before in three chambers. In one of these, the infusion remained perfectly pellucid; there was no trace of any organism to be seen. In each of the other chambers one of the three tubes gave way. Each chamber contained three tubes; so that out of nine tubes containing an infusion of fungus, seven proved to be intact, entirely uninvaded. Therefore, whatever argument or presumption was raised by the first chamber in regard to the idea that life was spontaneously generated in it, was entirely destroyed by the deportment of the other chambers. Seven out of the nine remaining intact, was sufficient to show that it was some defect in the experiment that caused the first chambers to give way so utterly. I continued the experiments, and inasmuch as fungi disappeared on the approach of winter, other substances were chosen. I took cucumber and beetroot, having special theoretical reasons for doing so, and prepared infusions of them with the aid of my excellent assistant, Mr. Cotterell. We placed these in our chambers as before, boiled them for five minutes, and abandoned them to what I supposed to be the moteless air within. Again, to my surprise, an infusion of beetroot in one chamber, and an infusion of cucumber in another, broke down. All the tubes became turbid and covered with this peculiar fatty scum. Other chambers were then tried. I had begun to suspect that we were operating in a contaminated atmosphere; that my infusions were in the midst of a pestilence which it was hardly possible to avoid. The consequence was, that I withdrew the preparation of the infusions from the laboratory downstairs, and I went to one of the highest rooms in the Royal Institution, had the infusions prepared there, and introduced into the cases, which were afterwards boiled in the laboratory below. There were a great number of these cases. The substances chosen were cucumber, beetroot, turnip, and parsnip. Great care was taken to have the infusions properly prepared, and to have them rendered as clear as possible. To give you an idea of the care taken, I may mention that the infusions of turnip and beetroot were passed through twenty-four layers of filtering paper, and were thereby rendered clear; that the infusion of cucumber was passed through one-hundred and twenty layers of filtering paper, and thereby rendered clear; and that the infusion of parsnip was passed through three hundred layers of filtering paper, and it was still opalescent. The suspended particles were so small that the filtered paper had no power whatever to arrest them, and the finest microscope ever made would have proved powerless to exhibit the individual particles that produced this opalescence. Notwithstanding all this care, the chambers containing these infusions in three days became filled with bacterial life. They were turbid, covered with scum, and showed all evidences of putrefaction. This was on November 20th. On November 25th, we went upstairs and prepared another chamber, or a series of chambers. When the tubes containing the infusions were placed in the oil-bath, the liquids within the tubes opening into the case of course boiled, steam was discharged into the case, the air of the case being thereby rendered warm. It was found that on the cessation of the ebullition, although the pipette was immediately plugged with cotton-wool, and the bent tubes also plugged with cotton-wool, still, in consequence of the contraction of the air within, there was a considerable indraught. Last year, we found invariably that the interposition of the cotton-wool entirely sifted this entering air so as to arrest any germs of seeds that it might contain. I thought, however, in this case, that the germs might be carried in by the suction when the air of the chamber contracted. In the former case, we operated after having filled the chamber with the infusion, and boiled it in the laboratory; in this case, we took the additional precaution of boiling the infusion upstairs, and taking care that it was properly plugged with cotton-wool. But here, again, notwithstanding this augmented care, the infusion utterly gave way, and showed those evidences of life that had distracted me previously. When I say distracted, it is not meant that I was in the least degree daunted or perplexed about it. I knew perfectly well that the matter would be probed by and by. On November 27th, a new chamber was constructed containing cucumber and turnip. Particular care was taken with the stopping of the pipette, and also the bent tubes opening into the atmosphere. In one instance about this time, it was noticed that the infusions in the tubes within the chamber opening into the moteless air, or at least what I supposed to be the moteless air, fell more rapidly into a state of putrefaction, became more rapidly covered with scum, than the tubes exposed in the air outside. When the tubes containing precisely the same infusion were exposed to the air outside they were perfectly clear, while those within were turbid and covered with scum. This brought to my mind an experiment made the previous year with trays placed one above the other. It was found that, when two trays were placed one above the other, although the upper tray had the whole air of the room for its germs to deposit themselves, the under tray was always in advance of the upper in the development of life. The reason was simply this. The air in the under tray was less agitated, and this floating matter had time slowly to sink in the infusions. There was no other solution possible than that, by some means or other, the germs had insinuated themselves into my chamber, and that these germs, sinking slowly through the unagitated air of the chamber, were able to produce the effect within, in advance of the effect produced upon the openly exposed tubes without. On November 27th, I had a similar case, and also on November 30th, and on December 1st. The chambers were prepared and filled with all care, and yet the infusions broke down, became turbid, and were covered with scum. I then had a number of tubes filled with infusions, and sealed them hermetically. They were exposed in an oil-bath, and heated for a quarter of an hour to a temperature of 230 deg. Fahr., for I wanted to see whether these effects were due to any germs of life in the infusions themselves. This superheated cucumber-infusion was introduced into the chamber, and it was found that the superheating of the infusion did not even retard the development of life. In two days, every tube of the chamber was swarming with bacteria. I then passed on to another system of experiment pursued last year, that is, the exposure of the infusions to air calcined by passing a voltaic current through platinum wire, so as to raise the wire to a state of incandescence. Such arrangements are here. We have underneath this shade two wires, and stretching from wire to wire we have a spiral of platinum. Passing a voltaic current through the spiral, it was found last year that five minutes of incandescence were sufficient entirely to sterilize and destroy all germs contained in this air, and to protect the infusions underneath from all contamination; the time of incandescence was doubled this year. The wire was raised as close to the point of fusion as possible; still, notwithstanding all this additional care, the infusions one and all gave way. I thought that there might be some defect in the construction of the apparatus. Here, you see, is an old broken apparatus containing infusions that have remained perfectly good since last year; but great pains were taken in having the apparatus of the most improved form. Still, notwithstanding all my efforts, the infusions broke down and became swarming with life. My attention was now very keenly arrested, and on December 1st, I scrutinized more closely than ever I had done previously the entry of the infusions through the pipette tube into the tubes opening into the chamber, and I noticed, at all events, a danger of minute air-bubbles being carried down along with the decending infusion. That caused me to adopt another mode of experiment; but previously to this, I fell back upon some of the infusions found so easy to sterilize the previous year. I operated upon beef, mutton, pork, and herring infusions, and found that even such infusions, which with the most ordinary care were completely sterilized last year, and are preserved to the present hour intact like the others, all gave way.

How, then, are we to look at these things? Here are results totally different from those that we obtained last year. You may ask me, perhaps, "Why do you not loyally bow to the logic of facts and accept the conclusion to which those experiments apparently so clearly point? Why do you not regard them as a demonstration of the doctrine of spontaneous generation? Is there any other way of accounting for it than by a reference to this doctrine?" You may ask whether I was held back by prejudice from accepting this conclusion; whether I was held back by a love of consistency, or by the fear of being turned into ridicule and sneered at by those whom I ventured to oppose on a former occasion. Ladies and gentlemen, there is a title which I believe, as the generations pass, will, if the owners of the title are true to themselves, become more and more a title of honour—that is, the title of a man of science; and of that title I should be utterly unworthy were I not prepared to trample all influences and motives such as those mentioned under foot, and were I not ready, did I conceive myself to be in error in what was brought before you last year, to avow here frankly and fully in your presence that error. I should be unworthy the title of a scientific man if my spirit had not been brought into this state of discipline as to be able to make such an avowal. Why, then, do I not accept those results as proving the doctrine of spontaneous generation? The celebrated argument of Hume comes into play here. When I looked into all my antecedent experience, and into the experience of other men for whom I have the greatest esteem as investigators, it was more easy for me to believe the error of my manipulation, to believe that I had adopted defective modes of experiment, than to believe that all this antecedent experience was untrue. It was my own work that was thus brought to the bar of judgment, and my conclusion was, that I was far more likely to be in error than that the great amount of evidence already brought to bear upon the subject should be invalid and futile. Hence, instead of jumping to the conclusion that these were cases of spontaneous generation, I simply redoubled my efforts to exclude every possible cause of external contamination. This was done by means of doing away with the pipette altogether, and using what we call a separation funnel. Here you have a chamber with a pipette entering. This pipette tube has not a bulb or mouth such as you have here; it is simply closed by a tube of India-rubber, and that again is closed by pinch-cock. Now, here we have an infusion of hay. At present, this stop-cock stops it. I turn it on; it goes down: I turn it off, and this liquid column is now held by atmospheric pressure. This was introduced into the India-rubber tube, the India-rubber tube being first filled with the infusion, so that no bubble of air could get in. When the separation funnel was placed thus, and the cock was turned on, the liquid was introduced into the chamber without an associated air-bubble. Mr. Cotterell will show you the result of this severe experiment. Here is an infusion of cucumber, the most refractory of all infusions that I have dealt with. It was prepared on December 8th, 1876, so that it is between six and seven weeks old. Two days were sufficient to break down this infusion when contamination attacked it; but, by this more severe experiment, it is enabled to maintain itself as clear as crystal, although it has been there for six or seven weeks. You will see by the light behind that it is, as I have described it, perfectly clear. You will observe that the infusion is diminished by evaporation, but it is as clear as distilled water, and there it remains as the result of this severe experiment.

Let us now ask how it is that these curious results that I have brought before you were possible; how is it that the results of this year differ so much from those obtained previously. The investigation of this point is worthy of your gravest attention. I am now called back to the experiments with which the inquiry this year began. As already stated, it was begun in September, and, leaving out the earlier experiments, I passed on to October 30th. I have now to bring your attention back to the earlier experiments performed in the laboratory. They were suggested by the ingenious investigations of Dr. William Roberts, of Manchester, and by the subsequent investigation of a man to whom we are indebted more than to any other for the knowledge we possess of the different species of those small organisms that we call bacteria: I refer to Professor Cohn, of Breslau. Let me say that I entertain the very highest opinion of the intelligence and ability with which Dr. Roberts has carried out these experiments; they are in the highest degree creditable to him. This is the experiment to which I refer. Some chopped hay is put into a little can; it is raised to a temperature of 100 deg. to 120 deg.; it is kept for three hours, then poured off and filtered. Last year, we found that hay thus treated was sterilized by five minutes' boiling. I mean that, when it is exposed to the air that has this floating matter removed from it, it never shows any sign of microscopic life. Now, if you examine this natural hay-infusion with litmus paper, you will find that it turns the litmus paper red, showing that it is an acid infusion. Dr. Roberts found that acid infusions could be easily sterilized. He took a vessel with an open neck at the top and filled it two-thirds full with the infusion he wanted to operate upon; he then stuffed the neck with cotton-wool, and sealed it hermetically with a spirit-lamp above the plug of cotton-wool; he then placed it in a vessel containing cold water, and he gradually raised the water to a state of ebullition and maintained the boiling temperature for any required time. In that way, he avoided all commotion, all evaporation, all ebullition in the infusion. After he had placed the tube in this condition in the water, and subjected it to a boiling temperature for any required time, he took it out and simply filed across the neck and broke it off. Here you have the infusion practically exposed to the atmosphere. The plug intervenes to prevent the entrance of dust and still allows an interchange between the air of the bulb and the air outside. When Dr. Roberts took this acid infusion and neutralized it by the addition of caustic potash, he found it to possess the most extraordinary power of resistance to heat; he found that, in some cases, it required more than two hours to reduce this infusion to sterility; he also found that, in a particular case, it actually required no less than three hours' boiling to produce this effect. This was very different indeed from the results that I had obtained last year. I made many experiments with hay-infusion, and in every case we sterilized it by five minutes' boiling. I was led to take up the subject this year through the emphatic manner in which Professor Cohn corroborated the results of Dr. Roberts. I operated sometimes with tubes like those of Dr. Roberts, and sometimes with those which I call Cohn's tubes. These are formed by heating a certain portion of a test-tube and drawing it out so as to leave an open funnel above, a bulb below, and a narrow tube between both. These are Cohn's tubes. His method was this. He placed the tubes, as they are placed here, in boiling water, and when they had been subjected to a boiling temperature for a sufficient time, he simply lifted them out. He found a certain amount of water condensed upon the neck of the bulb; he waited one or two minutes until that evaporated, and then quietly plugged his tube with cotton-wool, and he thought that this was perfect immunity against the entrance of contamination; and Professor Cohn is very emphatic in saying that there is no thought of contamination from without in pursuing this method of experiment. I operated upon a great variety of hay-infusions, and after a time, by pursuing with the most scupulous exactness the method laid down by Dr. Roberts and Professor Cohn, it was possible for me, by practice, now to corroborate and now to contradict them. It is perfectly useless to bring forward before public assemblies merely opposing assertions, so that I did not really content myself with falling back upon the results I obtained last year, but tried to get some knowledge as to whence the differences arose which showed themselves between me and these distinguished men. Here are tubes of alkalized hay, some of them subject to a boiling temperature, not for three hours, but for ten minutes, and they are perfectly brilliant; there is not the slightest evidence of life in them; they have been entirely sterillized by an exposure to a boiling temperature for ten minutes. If I illuminate them, you will find that these infusions are perfectly brilliant; there is no turbidity that gives any sign of the production of animalcular life. These tubes have remained there for three months perfectly intact, uninvaded by those organisms which were invariably found both by Dr. Roberts and by Professor Cohn. Again, we turn to another series of tubes, and find that every one of them has given way. Thus I went on ringing the changes, until, as I have said, it was in my power, by pursuing with undeviating fidelity the mode of experiment laid down by Dr. Roberts and Professor Cohn, to get at one time a contradiction and at another time a corroboration of their results.

And what was the meaning of these irreconcilable contradictions? The meaning was this: when we came to analyse these various infusions, we found that those that were sterilized by a boiling of from five to ten minutes were invariably infusions of hay mown in the year 1876, whereas the others were infusions of hay mown in 1875 or some previous year. The most refactory hay-infusion that I have ever found was in the case of some Colchester hay five years old. Now, what do these experiments point to? The answer may be in part gathered from an observation described in the volume of the *Comptes Rendus* for 1863 by one of the greatest supporters of the so-called doctrine of spontaneous generation. A description is there given of an experiment that was made by the wool-staplers of Elbœuf. They were accustomed to receive fleeces from Brazil, which were very dirty, and had, amongst other things, certain seeds entangled in them. These fleeces were boiled at Elbœuf sometimes for four hours; and the seeds were afterwards sown by some of these expert fellows that had to deal with the fleeces, and were found capable of germination. The thing was taken up by Pouchet. He gathered these seeds, exposed them to the temperature of boiling water for four hours, and then examined them closely; and he found (and I recently made an experiment which showed the same thing to be true with regard to dried and undried peas) that the great majority of the seeds were swollen and disorganized, while the others were scarcely changed; they were so indurated and perhaps altered in the surface as to prevent the liquid from wetting them. At all events, a number of them appeared to be quite unchanged. He separated these two clases of seeds and sowed them side by side in the same kind of earth. The swollen seeds were all destroyed; there was no germination; but in the case of the others there was copious germination. Here, then, you have these seeds proved to be capable, by virtue of their dryness and induration, of resisting the temperature of boiling water for four hours. There is not the slightest doubt that, if time permitted, I could heap up evidence of this fact, that the wonderful sterility of this old hay is due to the induration and desiccation of the germs associated with it. Here you have three tubes containing cucumber infusion of crystalline clearness; they have been simply subjected to a boiling temperature for ten minutes; they have been completely sterilized, and they are as clear as when the infusions were first introduced into the tubes. On the other hand, here are tubes that have been subjected to a boiling temperature for five hours and a half showing a swarming development of life. What is the reason of this difference? The reason depends entirely upon the method of experiment. When Dr. Roberts filled his bulbs, he simply poured in his infusion, plugged his tube, sealed it, and subjected it to a boiling temperature. Not only did the liquid contain germs, there was a quantity of air above the liquid, and the germs were diffused in the air. Germs thus diffused in the air are very differently circumstanced from germs diffused in a liquid: they can withstand for hours a boiling temperature; whereas that selfsame temperature, brought to bear upon germs immersed in liquid, destroys them in a few minutes. And why do these tubes differ? The reason is to be sought entirely in the method of filling the tubes containing the clear infusions. Take one of Dr. Roberts bulbs. You see that the top is united to a T-piece with a collar of India-rubber. This comes down and ends in the neck of the bulb. Here is an air-pump, and here is the end of the T-piece surrounded by a tube of India-rubber, and here is a pinchcock to close that tube of India-rubber. If you open the pinchcock and work the air-pump with which this end is connected, it is completely exhausted. You may allow it to be filled with air; you may then open the pinchcock; the air will enter through the cotton-wool, and will fill the bulb. In this way, you get the bulb filled, not with common air, but with filtered air. This process is carried on three or four times, so as to make sure that the common air has been displaced by the filtered air. We will suppose that I detach the tube from the air-pump, and other precautions taken. At present, you see the bulb is empty. Taking an infusion of hay, I put the end of the T-piece into the infusion to be introduced into the bulb. The bulb is dipped into hot water; the air expands, and it is driven out. Simply introducing our bulb into cold water, the air shrinks, and by atmospheric pressure the liquid is driven into the bulb. Again we drive the air out, and, by a few operations of this kind, we find that we can charge our bulb with a very great degree of accuracy. You can see the liquid in the bulb at the present time. In this way we charge a bulb which has had its common air and floating matter removed with our infusion. When it is charged, it is very carefully removed, and great precautions are taken so as to prevent any indraught of air. For instance, it is always removed from the cold water, so that, when it is lifted up into the air of the laboratory, a slight expansion shall take place, so that the motion of the air shall be from within outwards, instead of from without inwards. In that way we can, by careful manipulation, obtain bulbs devoid of this floating matter. These are the bulbs you now see before you showing this beautifully pellucid infusion.

Were this a biological investigation, and not a physical one, I should feel myself out of my element in dealing with it. I leave the determination of the species of bacteria to others far more competent than I am. I can see these organisms and wonder at them when I see them through the microscope; but I have no ability or knowledge to classify them and divide them into species, genera, etc. But these are purely physical experiments, and it is only by such severe experiments that this question can be freed from the haze and confusion in which it has been hitherto involved. Even the celebrated Professor Cohn—I say it with the greatest regard and respect for him—appears to have no adequate notion of the care necessary to be taken in experiments of this kind. To lift a tube out of the boiling liquid, and allow it to remain quietly in the air, the entry of the air taking place from without inwards, and then, after one or two minutes' exposure, to plug it with cotton-wool and say that no contamination can reach it, is in my opinion a great mistake. He could not, but by the merest accident, get an infusion free from contamination by operating in this way. I have here tubes prepared according to his method. Here are some melon-tubes all putrid, all gone into a state of fermentation. I ask you to compare those with some other melon-tubes that I have operated upon in a different way and that are as clear as crystal. The others are all gone, simply through a defect in the mode of manipulation.

The defeats that I at first described to you were due entirely to the contaminated atmosphere in which we worked. It ought to be noted that, in the earlier experiments in this inquiry, the results were always in accordance with those brought before you last year. By degrees, however, masses of hay were introduced into the laboratory—old hay and new hay from various places; and they ended by rendering the atmosphere so virulently infective that everything was contaminated by the germs set afloat. It resembled the case of a surgical ward of a hospital, where gangrene and putrefaction have attained such a predominance that the surgeon has in despair to shut up his ward and abandon it to disinfection. Desiring to free myself from this pestilential atmosphere, I wrote to my friend the President of the Royal Society, Dr. Hooker, and I found that he was able to furnish me with a means of getting away from it. In Kew Gardens, there is a beautiful new laboratory, erected by the munificence of that most intelligent supporter of science, Mr. Thomas Phillips Jodrell. He, at his own expense, has had this beautiful laboratory built—being designed, I believed, by Dr. Thiselton Dyer. It is one of the neatest things I have ever seen, and it is to me a great gratification that the first experiments made in that laboratory were those to which I have now to refer. I broke away from the contaminated air of the Royal Institution. It is very well for you that I can tell you, that all the germs referred to are perfectly innocuous to human beings, for I have no doubt the air of this room is contaminated with them. A series of chambers was made—not of wood, for I wanted to get rid even of that, but of tin—and I would not allow Mr. Cotterell to carry those chambers into the Royal Institution at all. They were carried from the tinman's where they were made to the laboratory at Kew. There, with the greatest care, the tubes were treated first with carbolic acid and then washed with water, and then with caustic potash, to get rid of all traces of carbolic acid, and finally drenched with distilled water. Carbolic acid, as you know, is a deadly foe to these germs. In this way I hoped that every contamination that might be adhering to the tubes would be destroyed, and that, having got clear of an infected atmosphere, we might get the same results as we invariably obtained last year. The temperature was raised to between 80 deg. and 90 deg., and once a little above 90 deg., so that the warmth was all that could be desired for the development of those organisms. It gives me the deepest gratification to find that what was foreseen has occurred, and that this very day these chambers have come back from Kew perfectly intact. They comprise the most refractory substances that I had experimented upon here. It was almost impossible to save a cucumber; I never did succeed in saving a melon-infusion from contamination, and from this so-called spontaneous generation. But here, when the air had been allowed to deposit all its motes, and when we were withdrawn from an infected atmosphere, as I have said, the chambers were returned with their infusions as clear as crystal. Mr. Cotterell will show you some of them. You will see that one of these is muddy and turbid, and it has a deposit at the bottom. These are all dead bacteria, and the muddiness is due to swarming baterial life. Here you have two infusions perfectly clear. Why did the other tube give way? When we came to examine it, a little pin-hole was found at the bottom of the chamber, and through that pinhole the germs got in. Here is a melon-infusion; and, in order to show you what would have occurred if the infusions had not been protected from the floating dust of the atmosphere, we have hung beside this case two tubes that have been exposed to the common air and have fallen into a state of utter rottenness. In this way, from the Jodrell Laboratory at Kew, we have had these cases returned with their infusions perfectly intact. Even in our infected atmosphere, when we subject our infusions to experimental conditions sufficiently stringent, we are able entirely to shut out contamination, and to show that spontaneous generation never occurs. When we get clear of our atmosphere altogether, this is a matter of perfect ease and facility; and we find in Kew Gardens that nature runs her normal course.

The Pharmaceutical Journal.

SATURDAY, FEBRUARY 3, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

VEGETABLE DIGESTION.

THE proposition that certain plants have the power to exercise special digestive functions has excited much interest and elicited diverse opinions. In our own Journal the statement of Mr. DRUCE that *Saxifraga tridactylites* must be added to the list of "carnivorous plants" called forth a protest from a respected correspondent, and we have reason for believing that more than one eminent British pharmacist is at present engaged in making observations on the subject. It may therefore be of interest to lay before them and others some recent results obtained by foreign investigators.

Since the discovery of the remarkable phenomena connected with the absorption of their food by so-called "carnivorous plants," the view has been rapidly gaining ground that there is in reality but little essential difference between the processes of the assimilation of food by plants and by animals. Professor CALDERON, of the Institute of Las Palmas, Canary Isles, has lately propounded the idea that plants do not, as is usually supposed, derive their nitrogen entirely from the nitrates and ammoniacal salts dissolved in the soil, but to a considerable extent also from the nitrogenous organic matter which is always floating in the air in a solid form. The purpose of the viscid hairs or glutinous secretion with which so many plants are provided, he believes to be the detention of this floating organic matter. To prove the importance of the solid particles floating in the air to the life of the plant, he deprived air of all its organic matter in the way described by Professor TYNDALL, and subjected some lichens to the access only of this filtered air and of distilled water, when he found all their physiological functions to be suddenly suspended. Professor CALDERON divides the nutrition of plants into three classes:—(1) *necrophagous*, the absorption of dead organic matter in various stages of decomposition; (2) *plasmophagous*, the assimilation of living organic matter, without elimination or distinction of any kind between useful and useless substances such as the nutrition of parasites; and (3) *biophagous*, the absorption of living organisms, such as that known in the case of insectivorous plants.

Professor ED. MORREN, of Liége, has contributed an important paper on vegetable digestion to the proceedings of the Royal Academy of Belgium. He commences by the assertion that digestion is not a function peculiar to "carnivorous plants," but that it is common to all living beings, vegetable as well as animal. Animal digestion is, he states, according to the most recent observations, a fermentation consisting essentially in a hydration, or transformation of colloids into crystalloids, this change being a necessary preliminary to absorption. It is caused by the action of certain substances known as ferments, which are especially abundant in particular secretions, such as the saliva, gastric juice, and pancreatic juice. In the same manner all plants digest, and the process is precisely analogous to that of animals, being in this case also essential before assimilation is possible. Such a transformation of a colloid into a crystalloid is illustrated in the ordinary change of starch into glucose, which takes place so commonly in plants; the active ferment in this case being diastase, which has been detected in barley, as also in the potato.

$$\underbrace{2\,(C_6H_{10}O_5)}_{\text{Starch.}}+H_2O=\underbrace{C_6H_{10}O_5}_{\text{Dextrine.}}+\underbrace{C_6H_{12}O_6}_{\text{Glucose.}}$$

$$\text{or } C_6H_{10}O_5+H_2O=C_6H_{12}O_6.$$

But, for the fermentation or digestion of albuminoids and other nitrogenous substances, a different ferment is required, and this we have in pepsine, which has been detected by Riess and Will, and other observers, in the viscid secretion of *Nepenthes*, *Drosera*, and other insectivorous plants. A similar substance has been observed in the latex of *Carica Papaya*, and elsewhere in the vegetable kingdom. It seems probable, in fact, digestion is as widely diffused a phenomenon, and as various in its forms, among plants as among animals. It consists essentially in the transformation of the raw insoluble food-material (a colloid such as starch) into soluble crystalloids capable of assimilation. The process takes place chiefly in the reservoirs of reserve-material, such as seeds, bulbs, tubers, roots, the pith, and the bark. The nutrition of plants is, therefore, made up of three successive processes:—(1) elaboration, or the production out of its elements of carbohydrates, which can take place only under the influence of light; (2) digestion, consisting essentially in a hydration, such as the conversion of starch into glucose, associated commonly with evolution of carbonic acid, and accompanied by a molecular change which renders the product soluble and diffusible; and (3) assimilation, the absorption into the tissue of the substances thus prepared, accompanied usually by a loss of water, and the reversion of glucose to the condition of cellulose, a substance isomeric but not isomorphic with starch, and the consequent production of the cell-wall. Intussusception is, therefore, a process which can only succeed digestion. No essential difference can, in fact, be maintained, between the manner in which animals and plants digest their food.

THE EVENING MEETING.

An Evening Meeting of the Pharmaceutical Society will be held on Wednesday next, February 7th, when the following papers will be read:—"On the Admixture of Veratrum with Valerian Root," by Professor Bentley; "The Colouring Matter of the Petals of Rosa Gallica," by Mr. Harold Senier; "Note on the Action of Dilute Nitric Acid on Brucia," by Mr. W. A. Shenstone; "The Pharmacopœia Test for Quinine Sulphate," by Dr. B. H. Paul. The Chair will be taken at half-past eight o'clock precisely.

"CASTOR OIL LOZENGES."

An anonymous writer in the *Lancet* calls attention to the extensive sale of so-called "castor oil lozenges," which he says are largely used by pregnant women of the lower class, and commonly given to children in the east of London as a pleasant aperient. In the letter it is implied that each lozenge contains three grains of calomel, and the writer states that he has just seen a severe case of mercurial salivation in a young girl who had taken half-a-dozen in two days. If it be true that the lozenges have the composition suggested, and are taken to the extent stated, it is almost a wonder that it is a single case that is reported and not a score.

A BUTTER TEST WANTED.

The *Sanitary Record* states that a prize of 300 francs is offered by the Food Bureau of the Leipzic Pharmaceutical Society, for the discovery of a "practical and certain method for the detection of the adulteration of butter with other fats." The papers of competitors are to be sent not later than the 30th of September next, to Herr Apotheker Kohlmann, Leipzic. They are to be marked simply with a motto, and accompanied by a sealed envelope bearing the same motto, and enclosing the name of the author. The copyright of the successful prize essay is to become the property of the Society giving the prize.

THE METRIC SYSTEM IN PRESCRIBING.

We learn from *New Remedies* that the movement among the physicians of New York in favour of the use of the metric system in prescriptions appears to be growing. We mentioned recently that it had received the unanimous endorsement of the Medical Society of New York; its principal advocates are, however, as might be expected, to be found among the younger men.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A meeting of the above Association will be held at 17, Bloomsbury Square, on Thursday evening, February 8th, at eight o'clock, when a paper on "The Diagnoses of the Principal Natural Orders" will be read by Mr. E. M. Holmes, F.L.S.

Transactions of the Pharmaceutical Society.

NORTH BRITISH BRANCH.

The third meeting of the present session was held in the Society's rooms, 119, George Street, on the evening of the 24th ult. Mr. William Gilmour, President of the Branch, in the chair. The following papers were read:—

I. On the Composition of Ewes' Milk.

BY DR. STEVENSON MACADAM, F.R.S.E.,
Lecturer on Chemistry.

During the sessions 1874 and 1875, I directed the attention of the Society to a lengthened series of experimental observations which I had made on the composition of cows' milk, both from town and country dairies. At the same time, I had analysed various samples of goats' and ewes' milk, though the results of these experiments were not specially included in the papers read before the Society. The general results then arrived at were, that milk varied much in quality as yielded by animals of the same species, even when the kind of food, the housing, temperature, time of milking, etc., were the same—not to speak of exceptional causes, such as the period of calving—as in all cases the milk, immediately after dropping the young, was very rich in quality.

The average quality of the different milks was then found to be as follows:—

Per cent. by weight.	Town Dairy. Cows' Milk.	Country Dairy. Cows' Milk.	Goats' Milk.	Ewes' Milk.
Total solids . .	12·27	12·77	13·43	17·78
Solids not fat . .	9·69	9·89	9·12	12·06
Fat in solids . .	2·58	2·88	4.31	5·72
Ash in solids . .	0·71	0·71	0·73	0·94

The most striking part of the investigation being the richness of ewes' milk, not only over cows' milk, but even over goats' milk, which has long been regarded as of very rich quality. Indeed, whilst the goats' milk was similar to rich cows' milk in proportion of ingredients, the ewes' milk was nearly half again as rich as cows' milk in total solids and twice as rich in fat or butter element.

In order that more light might be thrown upon the relative superiority of ewes' milk over cows' and goats' milk, I arranged for a more extended series of observations, and my friend Mr. Lyal, of Caddonlee Farm, on the north bank of the Tweed, kindly agreed to place a number of sheep at my disposal during the month of May, when the pasture was in excellent condition and there was a good flow of milk.

Ten sheep were selected for the experiments, and they, with their lambs, were placed in a small field by themselves. The number of sheep was not sufficient stocking for the grass, so that the sheep may be regarded as being under more than ordinarily favourable circumstances for feeding. The grass was of third year's growth and was in excellent condition. The milk taken from each ewe was kept separate, and the following table gives the results of the analyses of the ten samples:—

Analyses of Milk from Ewes fed on Natural Pasture.

	Total Solids.	In 100 parts by weight. Fat in Solids.	Solids not fat.	Ash in Solids.
Ewe No. 1. . .	17·45	5·02	12·43	0·79
" " 2. . .	18·77	6·56	12·21	0·81
" " 3. . .	20·25	8·94	11·31	0·82
" " 4. . .	21·01	9·56	11·45	0·95
" " 5. . .	17·76	5·30	12·46	0·87
" " 6. . .	18·76	6·63	12·13	0·81
" " 7. . .	18·94	7·37	11·57	0·73
" " 8. . .	17·04	5·37	11·67	0·93
" " 9. . .	17·44	4·56	12·88	0·93
" " 10. . .	20·13	8·46	11·67	0·89
Average of all	18·75	6·77	11·97	0·85
Lowest . .	17·04	4·56	11·31	0·73
Highest . .	21·01	9·56	12·88	0·95

These results fully bear out the very rich quality of ewes' milk, even when the sheep are fed solely on natural pasture. Arrangements were now made to supply artificial food to the sheep in addition to the natural pasture, in order to observe how far the extra food would enrich the milk. The sheep Nos. 1, 2, and 3 were each supplied daily for a period of ten days with a pound weight of linseed cake; Nos. 4, 5, and 6 with a pound of cotton cake; Nos. 7, 8, and 9 with a pound of oats; whilst No. 10 received no artificial food. Excepting at the times when they were consuming the feeding stuffs, the whole of the sheep were grazing at large in the same field. At the end of ten days, the ewes were again milked, and the various samples gave, on analysis, the following results:—

Analyses of Milk from Ewes fed on Artificial Food and Natural Pasture.

		In 100 Parts by Weight. Total Solids.	Fat in Solids.	Solids not Fat.	Ash in Solids.
Linseed Cake.	Ewe No. 1.	21·32	9·79	11·54	0·87
	— 2.	18·87	6·63	12·24	0·85
	— 3.	16·28	4·67	11·61	0·87
Cotton Cake.	— 4.	22·17	10·15	12·02	0·84
	— 5.	19·33	7·63	11·70	0·88
	— 6.	20·65	8·56	12·09	0·91
Oats.	— 7.	19·44	6·96	12·48	0·87
	— 8.	22·20	10·48	11·72	0·96
	— 9.	20·13	8·41	11·72	0·77
	— 10.	20·75	9·40	11·35	0·88
Average of all		20·11	8·27	11·84	0·89
Lowest		16·28	4·67	11·35	0·77
Highest		22·20	10·48	12·48	0·96

In contrasting the above analyses with those given in the previous table, it will be observed that the extra feeding stuffs have not raised much the quality of the milk yielded by the ewes, either individually or collectively.

It was distinctly noticed, however, by the shepherd, that there was an extra flow of milk in all those ewes which received the artificial feeding stuffs, though to what extent the milk was increased in quantity could not be determined, as the lambs were still with the ewes. In one case, that of No. 3, the artificial feeding appeared to take away from the quality of the milk, though the animal remained in good health, and such can only be explained by a greater yield of the milk. The influence of the extra feeding will probably be better observed by stating the averages so that the peculiarities of each individual sheep may be counteracted by those of the other sheep. The following tables give the average of the quality of the milk before and after feeding with linseed cake, cotton cake, and oats.

Average Milk from Ewes 1, 2 and 3.

1lb. linseed cake each day.

In 100 parts by Weight.	Before feeding with cake	After feeding with cake.
Total solids	18·82	18·83
Fat in solids	6·84	7·03
Solids not fat	11·98	11·80
Ash in solids	0·81	0·89

Average Milk from Ewes 4, 5 and 6.

1lb. cotton cake each day.

In 100 parts by Weight.	Before feeding with cake	After feeding with cake.
Total solids	19·17	20·72
Fat in solids	7·16	8·78
Solids not fat	12·01	11·94
Ash in solids	0·88	0·91

Average Milk from Ewes 7, 8 and 9.

1lb. of oats each day.

In 100 parts by Weight.	Before feeding with oats	After feeding with oats.
Total solids	17·81	20·59
Fat in solid	5·77	8·62
Solids not fat	12·04	11·97
Ash in solids	0·86	0·87

From the above tables, it will be observed that the feeding with linseed cake made in these trials no practical difference in the quality of the milk; the feeding with cotton cake gave an increase of 1½ per cent. in total solids which was strictly due to the milk being extra rich in fat or butter element; whilst the feeding with oats gave the more decided increase, there being nearly 3 per cent. more total solids, due also to an increase in the fat. Of course, other sheep fed in the same way might have given results more or less differing from these, as undoubtedly the individual sheep have much to do with the quality of the milk, independently of the feeding.

One of the best sheep of the series for quality of milk was No. 10 ewe, which, fed merely on natural pasture, gave even at the commencement, very rich milk, and at the end of the trials yielded fully as rich milk as the average of the whole of the ewes which were under extra feeding. The following table will show this:—

In 100 parts by Weight.	Average milk from nine ewes under extra feeding. Commencement of trial	Termination of trial	Milk from No. 10 ewe fed solely in natural pasture. Commencement of trial	Termination of trial
Total solids	18·60	20·04	20·13	20·75
Fat in solids	6·59	8·14	8·46	9·40
Solids in fat	12·01	11·90	11·67	11·35
Ash in solids	0·85	0·89	0·89	0·88

The averages are more reliable than the individual milks, especially when it is remembered that the last runnings from the udder are richer in cream than the first runnings, and consequently if the udder of the sheep is nearly empty when the sample is taken, the milk will be richer and give a larger proportion of total solids, as well as of fat in solids; while if the udder is full, the milk will be less rich and yield a smaller percentage of solids and of fat.

Taking these experimental observations on the quality of ewes' milk as a whole, the results prove the very rich nature of the milk yielded either under good natural pasture, or under such supplemented by artificial food. The averages of all the trials gave as follows:—

Average quality of Milk from Ewes.

In 100 parts by Weight.	Commencement of trials.	Termination of trials.
Total solids	18·75	20·11
Fat in solids	6·77	8·27
Solids not fat	11·97	11·84
Ash in solids	0·85	0·89

These results establish satisfactorily the very rich quality of ewes' milk, especially in the fat or the butter element, and it remains for medical practitioners to determine how far a milk containing two to three times the quantity of fat found in ordinary cows' milk may be employed as an important article of diet especially in the case of invalids.

II.—THE PRESENCE OF WATER FLEAS IN DOMESTIC WATER CISTERNS.

BY WILLIAM IVISON MACADAM.

For some time I have directed considerable attention to the presence in domestic water supplies of a class of animals known by the name of "Water fleas." These animals belong to the division of the sub-kingdom Annulosa called Entomostraca, and are principally of two families—the first genus being of the family Daphniadæ, one of the divisions of the order Cladocera, and is the *Daphnia pulex*. The second is a member of the Legion Lophyropoda, belonging to the order Copepoda, of the family Cyclopidæ, and is called *Cyclops quadricornis*. These are the principal forms of water fleas, but there are varieties of these, and also members of other orders which occur less frequently.

The first of these little Crustaceans, the *Daphnia pulex*, is enclosed in a bivalve shell which is joined at the upper part, and is hingeless although capable of slight contraction. It is quite transparent and by means of the microscope the structure of the animal can be easily seen. The body is divided into two equal parts, (1) the head, and (2) the thorax and the abdomen which are in one. The head is outside the shell, and has a hard covering. There is only one eye, which, by means of very strong muscles, has a semi-rotary power. It is connected with the brain, and is composed of about twenty crystalline pear-shaped lenses. From the top of the head there are the larger antennæ, which from their branched appearance have won for the daphnia the title of the *arborescent flea*. These antennæ are composed at the base of one segment which is divided into two branches, the first of which has three segments, and the second four segments. From the junction of these segments we have many smaller branches furnished with minute setæ or hairs. The superior antennæ are small and evidently useless. They are larger in the male than in the female. The body is divided into segments, the first of which only is attached to the shell, thus leaving a space between the body and the shell which is used by the female as an egg repository and in which the eggs remain till hatched. There are five pair of legs, two of which seem to be respiratory, but all of which are useless for locomotion. The colour of the insect is black or red. The young undergo no transformation but, like the full grown animal, frequently moult.

In the *Cyclops quadricornis* the thorax and abdomen are very distinct. The thorax has four segments, the first of which is the largest. The abdomen is divided into six segments—the second and third of which are nearly joined in the female. The superior antennæ are shorter in the male than in the female and are articulated, each articulation being furnished with either one or two setæ. The antennules have four articulations all furnished with setæ. There is one eye of a blood red colour. The legs are five pair, four of which come from the thoracic rings, whilst the fifth pair start from the first abdominal segment. Besides these we find two pair of smaller legs coming from the first thoracic segment which are considered to be employed by the animal in seizing food and carrying it to the mouth. The tail has two elongated segments furnished with setæ. The colour of the cyclops is white or grey to almost black or red. In the female the eggs are deposited in two small sacs, one on each side, and coming from the joint between the last thoracic and the first abdominal segments. The eggs are 30 to 40 in number in each bag and remain in the pouches till hatched, a process which requires from the three to twelve days according to the temperature of the water. The young cyclops on emerging is quite unlike the adult, being a sort of little bag with three pair of legs. It moults often and every moult brings a change on the cyclops, until in about twenty days it assumes the full form.

Both these crustaceans, or water fleas, are found in Edinburgh water during summer in considerable abundance, more especially the cyclops. They may be obtained in the cisterns through the year, and there are now specimens exhibited before the Society which were taken from cisterns in Edinburgh and Portobello, all of which contain the cyclops. The daphnia species is never so common as the cyclops, and probably this is due to the fact that in the large collecting reservoirs the daphnia is found mostly near the shore and in shallow water, while the cyclops is to be had all over the loch, but specially off the shore, and are thus more likely to be drawn off by the supply conduits and pipes which carry the water from the reservoir at a low level.

All cisterns do not contain these forms of life. Wherever the sediment in the cistern is foul and decomposing, due to improper attention to the cistern, the fleas are not to be found. It is true that in all cisterns there is a deposit, but if they are properly looked after and regularly cleaned out, the sediment is not putrescent, and consists principally of earthy matter along with a proportion of oxide of iron. The latter appears to be favourable to the life of the water flea, owing probably to its power of aiding in the aeration of the water. The fleas are very delicate; are only found in good impounded waters, and they cannot survive extremes in heat or cold. They are to be found in the water supplies of all our towns when carefully looked for.

The paper was illustrated by diagrams and microscope preparations.

Provincial Transactions.

LEICESTER CHEMISTS' ASSISTANTS' ASSOCIATION.

The annual supper of the members of this Association was held at the society's rooms, Halford Street, on Friday evening last, January 26. Between thirty and forty gentlemen sat down. Mr. W. Clark presided, in the absence of the Mayor, who had been invited. The tables having been cleared the chairman gave the usual loyal toasts, which were duly honoured.

Mr. Henry Cooper gave the "Pharmaceutical Society," and in doing so remarked that it was some time since he was at the society's place, but he had pleasant recollections of what he did when he was there. He always found the examiners and everybody connected with the society very pleasant. They might consider the society as their *alma mater*, as they were governed by it in all things pharmaceutical, and they might as well take kindly to it as not. If they were not under the guidance of the Pharmaceutical Society they would perhaps be under the thumbs of the Medical Council, which would be far worse. He hoped the Pharmaceutical Society would long continue to prosper.

Mr. T. E. Butler responded, and said he thought they had not much fault to find with the Society, although it was rather hard upon their young friends. The examinations of the society were now very hard. He had thought at times that they had aspired rather too high, and it would, perhaps, be as well if they rested a little now and let the students get perfectly initiated into the learning and education that they were attempting to reach, and then in twenty years time they might go a step further; they would then probably be better prepared for it. Although a good many prizes had been gained by the members of the Association, he thought the examinations were very difficult for many of their young friends, but at all events the Pharmaceutical Society was doing good, and they must try and obey its rules and regulations.

Mr. Butler then proposed the toast of "The Leicester Chemists Assistants' Association," and said he was exceedingly pleased to find that there was such a society existing in Leicester, and that such a goodly number attended it. Old veterans, like himself, could not do much for them, but whatever he could do he would. They began very late in life and had not the pleasure of going up to London to pass the examinations of the Pharmaceutical Society, but the young men would have to do it, and there was no use mincing matters about it. He was glad to find that there were so many in Leicester who had passed the examinations, who were willing to assist the apprentices to pass theirs. They were aspiring to a very high standard, and it could only be reached by great energy and perseverance, and he wished he could help them more. He sympathized with them in the difficulties they had to encounter, and hoped they would long have Mr. Clark among them, as he was able to do them a deal of good. There were others also among them, such as Mr. Thirlby, who could help them very much. He hoped they would not withdraw their efforts but that the society would long continue to be very successful.

Mr. Clark responded, and said from the way those present had received the toast, he concluded that they had great interest in the welfare of the Association, and that they wished it to be firmly established and to see it more prosperous in the future than it had been in the past. He impressed upon all the members, especially the younger ones, the necessity of punctual and regular attendance at the meetings of the Association, for it was only by this that they could obtain a minimum of knowledge which it was necessary for them to obtain. By their regular attendance they would encourage the lectures and thus promote the best interests of the Association. The honorary members could also afford them very practical aid. He did not ask them for increased subscriptions, for though these were necessary he knew they would gladly give them all they required, but he wanted them to come amongst them occasionally if they could by any means find time. There was another way in which they could afford the assistants great aid. They all knew the difficulty there was to get anything like careful assistants, those whom they could depend upon, at a moderate salary, but if principals would tell their new assistants that such a society as theirs was in existence they would do it a good deal of good, and the knowledge that such an excellent Association as this was in existence in the town would no doubt draw many more clever assistants to the town. He would commend these thoughts to their honorary members, who he hoped would render all the aid they could in the future.

Mr. Henry Cooper proposed in eulogistic terms the "Mayor and Corporation," which was responded to by Mr. C. H. Butler.

Mr. Thirlby gave "The President, Vice-President, and Committee of the Association," and regretted the absence of Mr. Barron, the President, through illness. He was sure they all hoped Mr. Barron would recover and enjoy better health in future. He had rendered the society very great assistance during the time he had held the office of President, and during his enforced absence the Vice-President had occupied his place to the satisfaction of everybody. The Committee had the welfare of the Association at heart. That society was held up before the whole country as a kind of pattern that others should follow, and the *Pharmaceutical Journal* had called attention to it as being one of the most successful of the provincial societies. He hoped the society would always be as well spoken of.

Mr. Hammond, the Vice-President, returned thanks, and also expressed his deep regret for the absence of Mr. Barron. He believed the society now held a better standing than it did when he came to the town about two years ago. Whatever he had done for the society he had tried to do for its good, and the Committee had done all they could for its benefit. He hoped the society would be increasingly prosperous, and that it would continue to reflect credit upon the members and honorary members.

Mr. Rees proposed the "Honorary Members," and said he had never been to a town where the chemists had been so cordial in their relationship to their assistants, so early in their hours of closing, or so kind to their assistants as they were in Leicester.

Mr. Cadoux responded and said when he was an active member of the Association, he knew the subscription of the honorary members were very useful, and hoped they would continue, and that the honorary members would take the hints thrown out by Mr. Clark to-night.

Mr. Thirlby gave "The Class Teachers," and spoke of the valuable service rendered by them to the Association. The study of botany was becoming a stricter rule of the Pharmaceutical Society than it used to be, and if the Association could arrange a half-day outing sometimes for the practical study of botany, as was done in other places, he believed it would be attended with great good. He had no hesitation in saying that the principals in the town would be glad to give their assistants the time requisite, and it could be easily arranged on some future day.

Mr. Raynor responded, and said the teachers were happy to do what they could for the classes of the Association. He, himself, had obtained the knowledge he possessed at the Association's meetings, and he felt it his duty to impart it to others.

Mr. E. H. Butler proposed "The Chairman," which was responded to by Mr. Clark, who also announced that a number of letters had been received from gentlemen expressing their inability to be present.

The other toasts were "The Ladies" and "The Press." During the evening a number of songs were given by gentlemen in the company, which added much to the evening's enjoyment.

NOTTINGHAM AND NOTTS CHEMISTS' ASSOCIATION.

The annual supper of the members of this Association was held at the Flying Horse Hotel, on Wednesday, January 24th, when nearly forty gentlemen sat down. The chair was occupied by the President of the Association, Mr. J. H. Atherton, F.C.S., and the vice-chair by Mr. J. Lewis.

After the usual loyal toasts had been given by the Chairman, Mr. R. Fitzhugh, F.C.S., proposed "Success to the Pharmaceutical Society," and coupled with it the name of Mr. Atherton, one of the Council of that Society, who suitably responded.

The toast of the evening, "Success to the Nottingham and Notts Chemists' Association" was then proposed in complimentary terms by Mr. H. Major, B.A., B.Sc., and it is almost needless to say it was heartily drunk.

The next toast on the list was the "President, Vice-President and Council," which was given by Mr. G. Shepperley, and responded to by the President.

Mr. Lomas next proposed "The Treasurer," to which Mr. J. Rayner responded; the health of the Hon. Secretary was next proposed by Mr. C. A. Bolton and responded to by Mr. Roberts Jackson. The remaining toasts were "The Teachers of the Science Classes," "The Vice-chairman," "The Visitors," and "The Ladies."

In replying to the toast of "The Visitors" Mr. F. J. Clarke, of Lincoln, whose name was coupled with it, very kindly promised a donation of £10 to the funds of the Association.

A good selection of songs, duets, etc., by efficient vocalists, accompanied by an excellent pianist, agreeably diversified the proceedings, and a most pleasant evening was concluded by singing the National Anthem.

Proceedings of Scientific Societies.

NEWCASTLE-UPON-TYNE CHEMICAL SOCIETY.

At the general meeting of this Society on the 21st of December, Mr. B. S. Proctor described a slight modification of the customary form of percolator, to adapt it to the exhaustion of small quantities of opium, etc., in analysis. It consists of the usual cylindrical tube and receiver, with the addition of a cylinder of tin plate or other suitable material, closed at both ends, fitting loosely within the percolation tube; the object being to get a slightly increased hydrostatic pressure with a small quantity of solvent. The substance to be exhausted diffused through a small quantity of the solvent, is poured into the glass tube, and then the tin tube being brought down till it touches the top of the liquid, its position is fixed, and more of the solvent is added. As this addition occupies the narrow space between the two cylinders, a head of 6 or 8 inches is obtained with a small quantity of liquid. This arrangement has also the advantage of permitting fresh additions of solvent without their mixing with that portion which by contact with the marc has become charged with extractive.

Mr. Proctor also described the following luting and washers for ether, sulphide of carbon, or other volatile liquids.

No. 1.		No. 3.	
Clay	30	Clay	5
Water	3	Gelatine	2
Glycerine	8	Water	2
		Glycerine	6
No. 2.		**No. 4.**	
Clay	30	Felt.	
Gum Tragacanth	1	Gelatine	2
Water	3	Water	2
Glycerine	8	Glycerine	6

Where a clay luting is required to retain its impervious character for a length of time, the addition of glycerine by preventing its drying imparts that character; but if glycerine and clay alone are used, the mass becomes softer by exposure, from the absorption of moisture. In the luting No. 1, the glycerine and water are present in such proportion as to give it little tendency to become either harder or softer.

A joint made with No. 1, if not kept rigid, ceases to be tight; but No. 2 will allow of a little motion, especially if rather more moist. No. 3 gives more flexibility, but requires to be applied warm, and of course will not resist heat—even a gentle heat—in use.

The presence of the clay makes the gelatine less fluid while warm, and consequently more convenient in application. Fluidity is still more completely got rid of in the following. No. 4 takes the form of a washer, and may be applied warm to delicate apparatus, or cold where mechanical pressure can be used freely. It appears to be quite impervious to the vapour of ether. The felt is simply soaked on the melted gelatine and glycerine, and the superfluous quantity pressed or drained out. Corks and bungs may be saturated with the same compound by being boiled in it for half an hour, and kept submerged till the temperature has fallen considerably. If then drained, and the superfluous jelly rubbed off the outside, they are in a condition suitable for stopping vessels of ether, sulphide of carbon, or benzine.

Glass stoppers may be lubricated with this glycerine jelly in some cases where oily lubricants would be objectionable.

Probably casks might advantageously be lined with a similar compound before being used for petroleum or coal oils.

THE SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A meeting of the above Association was held at 17, Bloomsbury Square, on January 11, 1876, Mr. Harold Senier, Vice-President, in the chair, when Mr. W. Ralph Atkins read a paper on "Faraday," of which the following is an abstract:—

Michael Faraday was born near Manchester Square in 1791, and obtained his first situation at the age of eighteen, in a bookseller's shop in Blandford Street. After a year's employment, in consideration of his faithful service, he was taken as an apprentice without a premium. He attended his first lectures on Natural Philosophy in 1809. At the expiration of his apprenticeship, he obtained the post of laboratory assistant to Sir Humphrey Davy, at the Royal Institution, with a salary of 25*s*. per week, his duties being to assist the lecturers, and to clean and dust the instruments and models in the glass cases. Not content with discharging these somewhat menial duties, he re-arranged the mineralogical collection, and was soon engaged extracting sugar from beet-root, making bisulphide of carbon, and other duties not strictly required of him. Soon after his appointment, he accepted an offer of Sir H. Davy's to travel with him on the continent, as his amanuensis, and travelled for a year and a half. In 1815, his engagement at the Institution was renewed with an increased salary of £100 per annum. He gave his first lecture in 1816, and in the same year the *Quarterly Journal of Science* published his first paper on an analysis of some native caustic lime from Tuscany.

At the age of twenty-seven the whole of Faraday's spare time was occupied in manufacturing rare chemicals, and in original investigations. Chlorine, iodine and naphthaline, were all studied by him. He tried for a long time to harden steel by alloying it with platinum and the rarer metals, but was more successful in the sciences of magnetism and electricity. In 1820, he was made honorary secretary to the Athenæum Club, and in the following year married Miss Barnard, the daughter of a silversmith of Paternoster Row. In conjunction with Stodart, he read papers on hydriodide of carbon, a new compound of iodine and carbon, and on the action of salts upon turmeric paper, before the Royal Society, but for forty years his great energies were concentrated in the investigation of the relation of electricity and magnetism to light. In 1836 he was appointed scientific adviser to Trinity House, and in 1837 he was president of the Chemical Section of the British Association.

Among the medals he received, were each of those at the disposal of the Royal Society, and the Grande Médaille d'Honneur from the French Exhibition; he was also made a member of the senate of the London University, although he had never passed through a university career. He received altogether ninety-five titles and marks of merit, including the blue ribbon of science, for in 1844 he was chosen one of the eight foreign associates of the French Academy.

Faraday's character combined reverence and kindliness with firmness; and although he went little into society, he was by no means unsocial. He delighted in nature, under two aspects more particularly, viz., in a thunder storm, and in watching the sunset fading into twilight. In fact, so fond was he of the former, that if the storm was at a distance, he would drive there in order to see nature in its awful beauty. He was also much interested in marine animals capable of giving shocks, and he proved that the gymnotus, or electric eel, has power to deflect a galvanometer, to make a magnet, and to give a spark. It is said that Faraday's answer to a young aspirant who asked the secret of his success as a scientific investigator was "The secret is comprised in three words—Work, finish, publish."

Faraday at one time had a theory that all metals would become magnetized if cooled down low enough; he experimented with cobalt and manganese cooled in a mixture of ether and carbonic acid, but the results were negative.

Faraday was pre-eminently a discoverer, he liked the name of "philosopher." He became acquainted as no man ever was with the varied forces of magnetism and electricity, heat and light, gravitation and galvanism.

In 1858, the Queen offered him a house at Hampton Court and there was spent the greater part of the rest of his life. He died August 26th 1867, and was buried in Highgate Cemetery.

The following incidents were communicated to the author of the paper by Mr. Barnard Proctor, of Newcastle, as having come under his personal notice. Faraday, one day, came unexpectedly into the presence of one of his little nieces, and found her ornamenting a cardboard box with sealing wax impressions which she had got off sundry letters. He entered into the child's play, taught her to dissolve sealing wax in spirit of wine wherewith to varnish the cardboard, and from time to time supplied her with seals till the box was completely covered. The box remains to this day a treasured monument of his loving kindness. This same niece, on another occasion, when ailing, expressed a great wish to see her uncle, a wish which the elder members of the household thought too childish to be mentioned to him, till the little one's persistence won the day, and he was sent for. Faraday said, "So earnest a desire should not be kept back." When he arrived the child had nothing to say beyond the great wish she had to see him. He said, to her that he was pleased to come to see her, and perhaps it would gratify her to hear that he had come direct from Buckingham Palace to see her.

On another occasion, going to see his sister, he found that she and the elder members of the household were out, but her son and two of his cousins were in the kitchen trying to make gas; so he joined in their experiments, until they were brought to a successful issue, and then left without waiting for his sister's return.

Dumas, when he gave the first "Faraday Lecture" of the Chemical Society spoke thus:—"Faraday is the type of the most fortunate and the most accomplished of the learned men of our age. His hand in the execution of his conceptions kept pace with his mind in designing them: he never wanted boldness when he undertook an experiment, never lacked resources to ensure success, and was full of discretion in interpreting results. His hardihood which never halted when once he had undertaken a task and his wariness, which felt its way carefully in adopting a received conclusion, will ever serve as models for the experimentalist."

Among the deep mines of the Durham coalfield is one called the Haswell Colliery. One Saturday afternoon, while the men were working in it as usual, a terrible explosion of fire-damp occurred; the roof fell in; and the suffocating gases rushed along the narrow passages, and overwhelmed ninety-five men with destruction. To inquire into the cause, Faraday and Sir Charles Lyell were sent by the Government. These two gentlemen attended the coroner's inquest, where they took part in the examination of the witnesses; they inspected the shattered safety lamps; they descended into the mine, spending the best part of a day in the damaged and dangerous galleries, and left a practical form of their sympathy with the sufferers on departing. Whilst down in the pit, an inspector showed them the way in which the workmen estimated the rapidity of the ventilation draught, by throwing a pinch of gunpowder through the flame of a candle, and timing the movement of the little puff of smoke. Faraday, not admiring the free and easy way in which they handled their powder, asked where they kept their store of it, and learnt that it was in a large black bag, which had been assigned to him as the most comfortable seat they could offer him.

Inventors and promoters of useful inventions frequently benefited by the advice of Faraday, or by his generous help. A remarkable instance of this was related by Mr. Cyrus Field. Before commencing his great enterprise of uniting the old and new worlds by the telegraphic cable, he sought the advice of the great electrician, and Faraday told him that he doubted the possibility of getting a message across the Atlantic. Mr. Field, wishing to settle this fatal objection at once, asked Faraday to make the necessary experiments, offering to pay him for his services. The philosopher declined remuneration, but worked at the question, and soon reported to Mr. Field—"It can be done, but you will not get an instantaneous message." "How long will it take?" was the next inquiry. "Oh! perhaps a second." "Well, that's quick enough for me," was the conclusion of the American, and the enterprise was proceeded with.

In conclusion, Monsieur Dumas thus speaks of Faraday—"There was nothing dramatic in the life of Faraday. It should be presented under that simplicity of aspect which is the grandeur of it. There is, however, one useful lesson to be learnt from the proper study of this illustrious man, whose youth endured poverty with dignity, whose mature age bore honours with moderation, and whose last years have passed away surrounded by marks of respect and tender affection."

At the conclusion of the paper, Mr. Atkins read the following letter from Professor Attfield:—

"London, 17, Bloomsbury Square,
"Jan. 25, 1877.

"Dear Mr. Atkins,—In response to your request for reminiscences of Faraday, I will give you two illustrations of his kind and encouraging manner towards young men aspiring to a position in science,—a trait of character such as is always met with in the truly great.

"On the 26th of October, 1857, Faraday called at the chemical theatre, St. Bartholomew's Hospital, to congratulate Dr. Frankland on his recent appointment to the Chair of Chemistry in the Medical School of that grand old institution. My chief had gone out, but Faraday came into the laboratory, looked at the lecture-room, and asked me, not questions relating to the researches of Stenhouse, whom illness had just driven from the school, nor any respecting those with which Frankland had already enriched chemistry, but questions concerning the lecture-table,—its supply of gas and water, the mode of getting rid of fuming products of the experiments, etc., and quite took possession of my young and therefore praise-greedy heart by appearing charmed with a little plan of mine of arranging the sets of lecture-diagrams, all out of sight but within an arm's length of the table. Without appearing to encourage me, his every word had that effect. On that day my diary notes were written in red ink.

"Nearly five years passed. Faraday never lost sight of me, and you may be quite sure I never lost sight of Faraday. I was often at the Royal Institution during that time, preparing the illustrations to Frankland's courses of lectures, or to his Friday evening discourses. Faraday frequently came into the quiet laboratory or the dimly day-lighted theatre, always with the same child-like spirit of inquiry—always patient, always amiable, always with a wealth of original suggestions respecting new modes of performing old experiments, or the most telling, truth-telling, modes of making new ones. And he never left me without increasing my respect, and I think I may add my love for him.

"In 1861 and the early part of 1862, Faraday had more than once talked with me about the then recently discovered spectroscope and the experimental demonstrations with it, which it was my duty to arrange and elaborate for Dr. Frankland's lectures. He thus got to know that I was myself working out what appeared likely to prove to be the spectrum of carbon and took some trouble to give my work such publicity in the best circles as I could never have secured without his kind and thoughtful aid. He invited me, on June 14, 1862, to show my spectra to, as he said, one or two of his friends who would be calling on him that day at the Royal Institution. I went and he introduced me to Major-General Sabine, the then President of the Royal Society, Colonel Philip Yorke, an ex-president of the Chemical Society, Gassiot, who was then making brilliant researches in electricity, and the eminent foreign physicists Becquerel and Plücker; Tyndall, on whom the mantle of the great seer has fallen, also was present: each of whom thereupon took the kindest interest in my experiments and my subject.

"On the east wall of the upper cemetery at Highgate there is a plain stone slab bearing the words "Michael Faraday, born 1791, died 1867." It is the monument of one who when a man, though ever occupied in unveiling to our sight the grandest agencies of nature, never forgot that he had once been an obscure youth, and never failed to aid and encourage the young and the struggling.

"Yours faithfully,

"JOHN ATTFIELD."

A discussion followed in which Dr. A. Senier exhibited specimens of Faraday's liquid chlorine. He showed also hydrate of chlorine in crystals. In explaining the method employed in their preparation, he remarked that the crystals were once supposed to be solid chlorine, but were shown by Davy to be a compound of chlorine with water. This discovery of Davy's led Faraday to make the experiments which resulted in the liquefaction of chlorine.

Parliamentary and Law Proceedings.

Brand's Essence of Beef.

In the High Court of Justice, January 25, Chancery Division, before Vice-Chancellor Sir Richard Malins, there was a motion on behalf of Thomas Dence and John James Mason, carrying on business as provision dealers in Little Stanhope Street, Mayfair, under the title of Brand and Co., for an injunction to restrain the defendant, Frank Mason, from selling any essence of beef, concentrated beef tea, meat lozenges or other meat essences, in tins, skins, boxes, or otherwise, having thereon labels or wrappers in imitation or only colourably differing from the labels or wrappers used by the plaintiffs, and from using the name of Brand, either alone or in combination with Mason or any other name in connection with essence of beef or other articles, manufactured or sold by the plaintiffs, from selling any of these articles in such manner as to represent or lead to the belief that the same had been manufactured by the plaintiffs. The facts of this case were that the plaintiffs' firm originated about forty-five years ago, when it was conducted by Mr. Henderson William Brand, and was about the year 1855 acquired by Mr. Withall, who, on the 29th of September, 1873, sold the same to the plaintiff, Thomas Dence for the sum of £5000. The business had always been carried on under the name of Brand and Co. The plaintiff, John James Mason was for fifteen years employed as manager of the business, and the defendant, Frank Mason, who is a brother of the plaintiff, J. J. Mason, was for about fourteen years prior to March, 1874, when he left the plaintiffs' service, employed as a journeyman in the business. In January, 1874, the defendant entered into partnership with a grocer in Sloane Street named Robert Brand, and he then commenced the manufacture and sale of essence of beef and other articles under the style of Brand and Mason. An application was made to the Master of the Rolls in September, 1874, to restrain this use of the name of Brand, and by an arrangement between the parties the defendant agreed to continue his business under the style of Mason and Brand; but soon after the partnership between the defendant and Robert Brand was dissolved, and Robert Brand required the defendant no longer to use his name in connection with the business. The defendant had, nevertheless, continued ever since to use his name, and the injunction now asked for was to restrain him from using the name of Brand any longer.

The Vice-Chancellor said he should grant an injunction to restrain the defendant from using the name of Brand in the sale of this essence of beef and other articles manufactured by the plaintiffs, also from the use of the words "Agent for Mason and Brand's Essence of Beef," on a shop front in the neighbourhood of plaintiffs, the words "agent for" being in small letters and the other words being made large and prominent.

Review.

Aids to Botany. By C. E. Armand Temple, B.A., etc. Baillière, Tindall, and Co.: London.

During the last few years there has been an evident tendency to the simplification of botanical study. To this fact the numerous elementary works on the science issued by different publishers bears witness. Not only has this been the case with books intended for the use of students and the public generally, but even in scientific works, fewer botanical terms have been used, and many which are found in manuals and class books are rarely met with in works on systematic botany. The little work before us, from its size and general appearance, seemed intended to belong to this category, but upon perusal it appears rather to be intended rather to form what would generally be understood by the term "a cram-book." In fact, on the title page we read that it is specially designed for students preparing for examinations, and the selection of natural orders at the end, which consists of those specially required for botanical examinations, as well as the extremely condensed definitions and the immense number of terms noticed, indicate that it is intended for such a purpose.

The preface expresses the hope "that it may prove of some real service to the already hard-worked students, before embarking upon works of greater magnitude." This little book reminds one of the kind of notes that are made in students' days; in fact, it is an epitome of all the terms met with in botanical handbooks. It is just the sort of book to which a student who had been through a course of botanical lectures would refer, in order to refresh his memory upon any forgotten point. As an introduction to larger works, it is of comparatively little use, for from the absence of illustration and examples, and the unequal and often hazy character of the definitions, it would be almost impossible for a beginner in the science to make much real progress.

Some of the explanations are very clear and easily understood. Thus, speaking of the leaf of Endogens, the author says, "the small veins cross at right angles, and the larger are parallel and straight." Imperfect definitions are, however, common throughout the book, and of mistakes there are not a few. Thus, under adventitious roots we find, "the Tuberous, corresponding to the *tap-roots* of the carrot." On other pages, "Thorns are formed by *some modified portion of a leaf*;" Phyllaries are individual bracts occurring in the order Compositæ;" "A Phyllode is the name applied to a petiole, which becomes flattened and assumes the function of a leaf whose lamina has fallen off." The author has evidently become confused over the sub-classes Calycifloræ and Corollifloræ, and in his definition of the latter, has made no provision for such natural orders as the Ericaceæ and Campanulaceæ.

Though evidently written with the design of helping students to pass examinations (the object of which unfortunately seems to be in the present day rather to puzzle the student than to ascertain the character of his knowledge), we cannot but feel that botany is not the author's forte.

Obituary.

Notice has been received of the deaths of the following:—

On the 3rd of December, 1876, Mr. Robert Moncrieff Rome, Pharmaceutical Chemist, Langholm, N.B. Aged 58 years. Mr. Rome had been a Member of the Pharmaceutical Society since 1853.

On the 17th of January, 1877, Mr. Charles Humphries, Chemist and Druggist, St. Mary's road, Garston, Liverpool. Aged 40 years. Mr. Humphries had been a Member of the Pharmaceutical Society since 1869.

On the 18th of January, 1877, Mr. John Price, Chemist and Druggist, Treforest. Aged 50 years.

On the 20th of January, Mr. John Handel Bland, Pharmaceutical Chemist, Stourbridge. Aged 70 years. Mr. Bland was Local Secretary of the Pharmaceutical Society, of which he had been a Member since 1857.

Correspondence.

Milk of Sulphur.

Sir,—Although I do not find much in what is said by your correspondents, Messrs. Brown and Chipperfield, that ought to require further explanation and comment than have already been given in your Journal, I am unwilling to allow the appeal that has been made to me by the former, and some of the assertions of the latter of those gentlemen, to pass unnoticed. I can assure Mr. Brown that I am not aware of any change having occurred in my opinions with reference to the milk of sulphur question, other than the strengthening of convictions resulting from continued investigation of the subject. What I have said is that the term "milk of sulphur" has been and still is sometimes used as a synonym for "precipitated sulphur," but that the two terms have not entirely the same meaning, for while the latter is limited in its application to the article described under that name in the 'British Pharmacopœia,' the former has a double meaning, and although sometimes applied to precipitated sulphur, B.P., it is more generally employed in a sense in which it was officially used in the early part of last century, and in which it has ever since been used, to represent sulphur mixed with sulphate of lime. It seems hardly necessary to allude to the far-fetched suggestion of Mr. Brown that milk of sulphur made according to the Pharmacopœia of 1721, with lime and sulphuric acid, ought not to contain sulphate of lime, as the washing ought to be continued until that ingredient is all washed away; but the suggestion, founded as it has been upon an incorrect description of the Pharmacopœia process, shows what expedients the advocates of that side of the question are obliged to resort to. Even Mr. Chipperfield, who, in common with others, quotes, not the Pharmacopœia, but some commentary upon it, cannot accept the suggestion that the sulphate of lime was intended to be all washed away. I am glad to find that you have given in the last number of the Journal, at page 627, the exact Latin words of the Pharmacopœia process. Anything more than the word "edulcora" signifies, is not necessarily the meaning of the Pharmacopœia, but of some commentator upon it. Let practical men take the simple and concise terms of the process and construe them in accordance with common sense.

Much of the confusion and error which have been recently apparent in the statements published on this subject, have arisen from reference having been made, not to the Pharmacopœias themselves, but to annotated translations. I may perhaps on this account be excused for saying that without going further back than 1721, the only editions of the London Pharmacopœia that have appeared are those of 1721, 1746, 1788, 1809, 1824, 1836 and 1851. There were intermediate reprints, but in those there were no alterations except typographical corrections. The authorized works were all published in Latin, and the descriptions were generally given briefly under the Latin names of the articles referred to, without note or comment. Synonyms were but rarely inserted.

In saying that "lac sulphuris" or "milk of sulphur" has been used as a synonym for "precipitated sulphur" I do not intend to imply that after the adoption officially of the name "sulphur præcipitatum," for which a new process was given, the previously used name, "lac sulphuris," acquired a new meaning, or that the two names as used officially had strictly and entirely the same meaning. "Lac sulphuris, 1721," meant sulphur precipitated either with or without sulphate of lime, while "sulphur præcipitatum, 1746," meant sulphur with sulphate of lime, the alternative process for obtaining it without sulphate of lime having been omitted. Thus in one respect both the names had the same meaning, but the name "lac sulphuris" had a double meaning and might be used in either of the senses. Since the edition of the Pharmacopœia of 1721, the name "lac sulphuris" has not been officially used at all, and no new or altered definition has been given to it. Strictly, therefore, it still has the same meaning as it had in 1721. "Sulphur præcipitatum," which, in 1746, was directed to be made by a process which yielded the mixture of sulphur and sulphate of lime, had an altered process given for it in 1788, since which time the sulphate of lime has been excluded from it.

I am at a loss to understand the object of Mr. Brown's inquiry, "Why the words lac sulphuris, or milk of sulphur, were not inserted in the B. P., 1867," unless it be that, misled by Mr. Crow's mistake of an annotated translation of the Pharmacopœia for the Pharmacopœia itself, he concluded that lac sulphuris had been given as a synonym for precipitated sulphur in the London Pharmacopœia of 1851. As the question has been asked me, however, I will endeavour to answer it. Synonyms, as I have already said, were rarely given in the London Pharmacopœia, but they are freely given in the British Pharmacopœia. Whenever a preparation in the British Pharmacopœia is intended to represent, or to be substituted for, a preparation under a different name that has been ordered either in the previous edition of that work or in the London, Edinburgh, or Dublin Pharmacopœias, the preparation under its old name is inserted as a synonym. Now, lac sulphuris is certainly not inserted as a synonym under sulphur præcipitatum, which, if anything is to be inferred from it, indicates that sulphur præcipitatum was not intended to be substituted for lac sulphuris. Under the head of "antimonium tartaratum" we find inserted as synonyms, "antimonii potassio-tartras, Lond.," and "antimonium tartarizatum, Edin. and Dubl.," indicating that the new preparation might be used when prescriptions contained either of the old names. There are numerous other cases of a similar description, this being a special feature in the British Pharmacopœia. But now, if we turn to "*pulvis antimonialis*," which is the modern representative of what in the London Pharmacopœia had been called "*pulvis antimonii compositus*," we do not find this last name inserted as a synonym of the new one. So again, under "*tinctura rhei*, B.P.," we do not find *tinctura rhei composita*, Lond., as a synonym, although the new tincture replaced the latter; nor do we find "*pulvis comitis warwicensis*" given as a synonym of "*pulvis scammonii compositus*," although the former of these preparations, which was introduced into the Pharmacopœia with "lac sulphuris" in 1721, was the original from which the present "compound powder of scammony" has been modified.

The intention of the authors of the Pharmacopœia has been that where the names of old preparations are inserted as synonyms under those of their modern representatives, the new preparations may be used when the old names are employed in prescriptions, but this is not otherwise to be done. It would be incorrect, therefore, when *pulvis antimonii compositus*, or *tinctura rhei composita*, or *pulvis comitis warwicensis*, is prescribed, to use the preparations that are their representatives in the present Pharmacopœia. By a parity of reasoning also the pharmacist would not be justified in dispensing sulphur præcipitatum, B. P., if lac sulphuris were prescribed, without duly considering, and if need be, ascertaining by personal inquiry, whether that or the other preparation which the name represents was intended to be used.

Now there are two different classes of circumstances under which the term "*lac sulphuris*" or "milk of sulphur" may be presented to the druggist for interpretation, namely—

1st. When it is used in prescription by a medical man; and

2nd. When it is used by a customer in applying for the article it is intended to represent, in the ordinary mode of retail dealing.

1. Under the first class of circumstances, the question to be answered may present some difficulty, as I stated in my evidence at Runcorn. If, from knowledge previously possessed, the intention of the prescriber was known, that of course should be acted upon; otherwise, as the meaning of the term is ambiguous, it would be the duty of the dispenser to endeavour to ascertain what was intended to be used. But if there should be no means of obtaining this knowledge, and the dispenser is left to the exercise of his own judgment, he might be supposed to reason somewhat as follows. If the prescriber intended to order the precipitated sulphur of the present Pharmacopœia, why did he not use the only name that has been officially applied to that preparation during the last hundred years. The fact of his using a name which medically has been almost completely superseded—a name which has a double meaning, and which is now generally applied to the old preparation of sulphur with sulphate of lime—would seem to indicate that he intended that preparation to be used. A similar mode of reasoning would be pursued if *tinctura rhei composita* or *pulvis antimonii compositus*, or *pulvis comitis warwicensis*, were ordered by a physician in his prescriptions; but with reference to the first two of these latter names, there would be much less reason for interpreting them by referring to the Pharmacopœia in which they were used instead of adopting their modern substitutes than there would be in the case of lac sulphuris, because those names have been comparatively recently used in medical prescriptions, and their continued use might be ascribed to habit or forgetfulness, which could not be said of lac sulphuris.

2. With reference to the second class of circumstances, which are those alone that have any important significance, because it is very rarely that medical men prescribe lac sulphuris, the druggist should, I conceive, be mainly influenced by the requirements of his customers, subject, however, to the exercise of an intelligent discretion by which he may endeavour to influence the opinions of those who apply to him, if under a sufficiently strong motive he thinks he can do so for their benefit. I respect the motives of those who refuse to sell milk of sulphur containing sulphate of lime, although I think they are acting under mistaken ideas, which for several years past have been fostered by writers on materia medica, to whom the adulteration of milk of sulphur has been a sensational stalking-horse. If those writers had taken the pains to thoroughly investigate the subject, which I can find no evidence or indication of their having done, I believe they would have come to a different conclusion from that which they have adopted.

Mr. Chipperfield speaks very confidently of what the intentions were of the authors of the early pharmacopœias in altering the process for the preparation of precipitated sulphur, but he fails to explain the ground on which the scientific committee of revision in 1746 directed precipitated sulphur to be made with the admixture of sulphate of lime. I am quite ready to admit that the alteration afterwards made in 1788 had for its object the rejection of sulphate of lime, although I cannot agree with Mr. Chipperfield in saying that it was "to prevent the possibility of a person desiring to take a dose of sulphur introducing into his stomach at least as large a quantity of inert if not noxious sulphate of lime." The object of the Pharmacopœia is not to provide the public with medicines to be used on their own responsibility, although many of the medicines ordered are so used, but the immediate object is to define the medicines which medical men prescribe or require in the treatment of disease, and these medicines are generally administered not in the forms in which they are ordered in the Pharmacopœia, but after admixture as medically prescribed. Except in special cases, such as those alluded to by Mr. Pemberton, the precipitated sulphur in its unmixed state is better suited for the general purposes of the prescriber than it would be if previously mixed with what the prescriber may not wish to administer, although the addition, if made, might be neither noxious nor inert. The prescriber has the power and the knowledge to enable him to make such additions as may be required, but the non-medical public are in this respect in a less advantageous position. They have learnt, it is true, to mix cream of tartar with their brimstone and treacle, and they have also learnt from experience, what others with medical knowledge know, that milk of sulphur containing sulphate of lime has its aperient properties increased and modified, while its sensible characters are improved and the mixture is rendered better suited for administration by those who have neither the knowledge nor the appliances for making suitable additions to sulphur in other forms.

Mr. Chipperfield is quite entitled to the enjoyment of the opinions he may entertain in opposition to these views, but I do not think it is consistent with the exercise of the courtesy and forbearance due to those of his brethren who differ from him, and are equally capable with himself of forming a correct judgment on such matters, that he should compare the sale of an old and approved Pharmacopœia preparation under its proper name, to the sale, under the name of pepper, of what is a mixture of pepper with ground rice. Mr. Chipperfield speaks of the practice of the trade in a way that might induce a belief that the sale of the article he objects to is confined to a section consisting of those who are not first-class men. I can only say, if this is so, and perhaps Mr. Chipperfield has better means of judging than I have, that notwithstanding the information I have received from a large number, both of wholesale and retail druggists, I have been greatly mistaken and deceived.

In a class of men differing so greatly as do chemists and druggists, in the circumstances under which they are placed and the nature of the duties they are called upon to perform, it is necessary for individuals among them to be careful how they judge and may be disposed to condemn those differently circumstanced from themselves. The qualifications required for conducting a druggist's business in some localities are very different from what they are in others. The first-class dispensing chemist that Mr. Chipperfield speaks of, would be puzzled to interpret the provincial lingo, or to appreciate the local wants of the public in some parts of the country, while on the other hand, the druggist trained in such localities and qualified for the performance of all that is required of him there, would find himself oppressed with many doubts and difficulties if called upon to read and interpret the handwriting of the abbreviated bad Latin in which the last suggested combinations in scientific or eccentric pharmacy have been prescribed. The one is rarely puzzled with a prescription, while the other is never troubled with customers who must have a particular type of milk of sulphur, or if such customers present themselves, is willing to stand upon his dignity as a first-class chemist, and to draft them off to the second-class men, from whence they never return.

But the questions which, it appears to me, lie at the very core, and are the only questions that require solution, in connection with this subject, are,

1. Was the term milk of sulphur defined in the London Pharmacopœia of 1721, in addition to another meaning, to mean sulphur containing an admixture of sulphate of lime?

2. Has any altered definition been officially given to the term milk of sulphur since 1721? If so, when and where?

3. Has sulphur precipitated with sulphate of lime according to the P. L. process of 1721, been supplied to the public, under the name of milk of sulphur, continually from that date up to the present time?

4. Do the public, especially in some localities, when applying for milk of sulphur, often object to receive any other sort than that which contains sulphate of lime?

5. If a vendor, to whom no special instructions have been given by the purchaser, sells, under the name of milk of sulphur, an article which was officially ordered under that name by the London College of Physicians in 1721,—which has never been officially directed to be made in any other way than it was then directed to be made,—which from that time until the present has been recognized among dealers as one of the two forms in which milk of sulphur may be legitimately produced,—and which has been always, and is now, preferred to the other sort of milk of sulphur by a large proportion of that part of the public who are in the habit of using milk of sulphur,—can it be said that the vendor has sold "to the prejudice of the purchaser a drug which is not of the nature, substance, and quality of the article demanded?"

These are the questions that will have to be judicially determined, and the sooner the better.

T. Redwood.

17, *Bloomsbury Square*,
31 *January*, 1877.

Sir,—I have no wish to continue a controversy on the milk of sulphur question or to curdle the milk by unnecessary acidity, but Mr. Brown's style of writing was certainly very provocative of much sharper criticism than I administered; in fact much suggested itself at the time which on reperusal was cut down and mollified.

However, I trust you will allow me to make a few remarks on Mr. Brown's second letter. He says it is "absurd to talk about a hogshead of water"—"as required to clean a pound of selenited lac sulphuris." But he says calcium sulphate is soluble in about 460 parts of water (Brande says 500). If there be 60 per cent. of calcium sulphate in milk of sulphur it would require 27·6 gallons of water as a minimum to hold in solution the calcium sulphate of one pound of milk of sulphur. I believe I am right in saying these saturation tables always refer to distilled water, and no doubt my experience is not unusual in finding that it is generally impracticable to dissolve the calculated quantity of a salt in ordinary water. Surely Mr. Brown would not suggest that the "lac sulphuris of bygone times" was washed with distilled water. It would also be misapplied "diligence" to attempt to "wash" up to the point of saturation. I certainly do not mean to try the experiment, but should Mr. Brown feel inclined to undertake the task of thus removing the calcium sulphate from one pound of milk of sulphur, my impression is still that he will not have much of the hogshead of water left unused.

He speaks of dissolving the "selenite." There is no selenite to dissolve. All selenite may be calcium sulphate, but it does not follow that all calcium sulphate is selenite. Selenite is a peculiar form of gypsum which itself is only one peculiar form of calcium sulphate. When selenite loses its peculiar physical conditions it ceases to be selenite. In coining an adjective, why not call it "gypsified" sulphur? This term would be more in keeping too with the "advanced (?)" view of the milk of sulphur controversy, for it has been a hackneyed expression to speak of persons swallowing plaster of paris when taking milk of sulphur. Surely it would be as appropriate to call charcoal biscuits, "adamantine biscuits," because of the relationship of charcoal and diamonds, as to speak of milk of sulphur as "selenited sulphur." But a part of the mystery is that Mr. Brown speaks of both "selenited sulphur" and "selenited lac sulphuris.'"

Another "misty cloud" is why Mr. Brown asks, "Does Mr. Symons think that calcium sulphate is easily sublimed?" Where can he find an expression in my letter to suggest such a question?

With regard to the "defying" paragraph of his second letter, I cannot now refer to the 1857 edition of Gray, but only point out that Mr. Brown speaks of precipitated sulphur, with regard to which I have no difference with him. What I, for one, protest against is this confounding of precipitated sulphur with milk of sulphur, a point on which it ought to be needless to enlarge, seeing that the question at issue has been so tersely, logically and unanswerably put in its common sense light by so disinterested and influential authority as the *Lancet*.

I cannot see the force of the question as to scammony and jalap. It may as well be asked why mix sulphate of potash with pulv. ipecac. co., or phosphate of lime with pulv. antim.? The only reply to such a question is, that it is found practically useful and convenient; and so I contend has the combination (not the mere mixing) of sulphur and calcium sulphate as they are blended in milk of sulphur.

I cannot plead guilty to the charge of "ungentlemanliness" in protesting against the interference of "half-instructed analysts." Although I have not personally been brought into collision with the nuisance, some of our brother tradesmen have been called on to suffer innocently, but severely, through the officious meddling of these new brooms, attempting to justify their appointment and to advertise their importance.

With regard to Mr. Chipperfield's letter, I have only to say that I had intended in my first to refer to the object of washing "till it becomes insipid" as evidently intended to remove all the free acid. This statement quite favours my view of the matter.

As to the rest of Mr. C.'s letter, every point of his is so conclusively met by the quotation from the *Lancet* and the evidence of Professor Redwood and Messrs. Pemberton, Evans and Matthew Bell, as reported in the Runcorn case, that it would be a useless waste of paper and time for me to go over the matter again, as of course the opinions of such authorities must have far greater weight than any remarks of mine. I will only say that the evidence of the above-named commercial gentlemen show that the "cute northerners" seem as "benighted" as the consumers of Devonshire dumplings. Moreover, there can be little doubt that some chemists have been frightened into giving up the sale of the "genuine old milk of sulphur" through this analytical hubbub.

W. Symons.

Barnstaple, Jan. 27, 1877.

Sir,—The milk of sulphur question is on all fours with the coffee question. I for one decidedly prefer chicory mixed with my coffee and believe it to be more whol esome than coffee alone. Decisions in abundance insist that when chicory is mixed with coffee, a label stating the admixture shall be duly affixed; any one selling milk of sulphur with the pet admixture of lime sulphate is bound to disclose the same. There is not one law for coffee and another for milk of sulphur. Depend upon it the lawyerd will make very short work of the appeal. Coffee unquestionably meant, formerly, the chicory admixture in practice, precisely the same as London milk meant cow produce and pumpenheimer.

George Mee.

Sir,—I did omit the word "translation" in my last letter; the quotation is correct.

This work was so generally used in all the pharmacies with which I have been connected that I thought it the best one to quote from, as being more commonly known and referred to than the Latin edition. The book in question was published before Redwood's translation of the 1851, and is entitled the 'Pharmacopœia of the Royal College of Physicians of London, 1851. Translated by a Physician. London 1851. Henry Renshaw, 356, Strand.'

Squire also, in his 1851 edition of the three Pharmacopœias, describes Sulphur. Precip. P. L., as "milk of sulphur. Also Garrod in 1868 and Royle and Headland in 1868.

EDWIN L. CROW.

CHEMISTS AND DRUGGISTS AND THE MEDICAL ACTS.

Sir,—In the *Pharmaceutical Journal*, December 30th, 1876, Mr. Fryer criticizes the paper read before the Leeds Chemists' Association, reported in the same Journal, December 23rd, and in a letter addressed to you on the 6th inst., I endeavoured to make the subject a little more easily understood. It is satisfactory to find that I have succeeded so far as to obtain from Mr. Fryer an admission in his last letter, that there is no definition of the business or profession of an apothecary in the Act of 1815, except in the 5th section. The assertion of your correspondent in his first letter, that "the Act must have been read in the dark" is evidently correct, but cannot be applied to the Leeds chemists. The same want of care in reading my paper has led him to express sorrow that he cannot convince me of the true position of the apothecary, whereas, if he will again refer to it he will find that this is properly understood and clearly expressed.

In referring to my letter he again exhibits an obscurity of mental vision, when he says that "Medicine," "Physic," and "Pharmacy," having a similar meaning. This arises from the fact that he has not observed the difference in the spelling of two words used throughout the Act, and which in the sentences where they occur convey quite a different meaning. I refer to practice and practise. In expressing an opinion as to the probable meaning of the word medicine, I qualified it by reference to one section only, and according to modern phraseology. There has therefore been no contradiction, and as Mr. Fryer has advanced no new facts to alter the case, the conclusion arrived at by the Leeds chemists remains in *statu quo*.

E. YEWDALL.

Leeds, Jan. 22, 1877.

SUNDAY LABOUR.

Sir,—If the President of the British Pharmaceutical Conference, when in Glasgow in September last, found reason, in a day's observations, to characterize as "derogatory" one of the aspects of pharmacy in this city, I fancy that were he to stay over Sunday in our city he would find great cause to apply the epithet to another phase of our business as it is conducted here. No one denies the necessity for druggists keeping their shops open for a short time on Sundays for the dispensing of prescriptions and the supply of various articles which are at times required in cases of sudden illness. That these requirements, however, do not justify the druggists of this city in keeping open their shops for so long as they do is clearly indicated by the fact that the establishments in which most dispensing is done are, without exception, open for the shortest time, and those in which scarcely any dispensing is done seem to have no particular hour for closing, and the lurid glare reflected from their show bottles may be seen dazzling the eyes of the most belated straggler as he saunters home to bed.

It may be asked, what is the reason of this? The reason would simply appear to be that the latter keep open in order to do a trade. Moreover, the trade which they continue to carry on in effervescing drinks, pick-me-ups and cigars is something wonderful,—in truth I suspect it to be the most profitable day that a goodly number of them have. They must find it pay or they would not contribute so liberally to their gas bills.

Profession, forsooth! Our calling may be so from Monday till Saturday, but on Sunday it is certainly, in many instances, reduced to a huckster's business. The Sunday hours in the better class establishments are, closed from 9 a.m. to 7 p.m., during the hours of church service. Deduct four hours for church service and six hours remain as the time during which they are open. Even these hours are largely in excess of the requirements of necessity.

An hour morning, afternoon and night would, in the writer's humble opinion, afford sufficient facilities, to those requiring medicines, for procuring them.

Besides, while druggists, who are supposed to be men of fair education, and of whom better things would naturally be expected, keep open shop on Sunday for the unlimited sale of "drinks," cigars and confectionery, it is scarcely fair to make a noise about Sunday trading by persons whose business it is to deal in these articles during week days. Surely our hours of duty during the week are sufficiently long and confining without making them more so by working all day on Sunday.

The effect of this system on those who are continually on duty must be exhausting physically and depressing mentally —no leisure being afforded for bodily exercise or intellectual improvement.

"No blessed leisure to read or think,
And scarcely time to sleep."

Were some influential member of our calling to initiate a movement for the curtailment of the hours of Sunday duty in our city, might it not be hoped that it would not be so difficult to secure unanimity in the matter of closing on this day as during the week?

ONE WHO DOES NOT LIKE TO "TRADE" ON SUNDAY.

Glasgow, Jan. 20, 1877.

"*Inquirer*" is referred to the rule respecting anonymous communications.

A. Young.—Glycerine Jelly.—The following has already appeared in this Journal:—

White Soft Soap . . .	4 oz.
Pure Glycerine . : .	6 ,,
Almond Oil	3 lbs. in Summer. / 4 lbs. in Winter.
Otto of Thyme	2 drachms.

Mix the soap and glycerine in a mortar, add the perfume to the oil, and rub it in gradually, taking care not to add the oil faster than it can be incorporated.

THE ADMIXTURE OF WHITE HELLEBORE WITH VALERIAN ROOT.*

BY PROFESSOR BENTLEY.

Honorary Member of the Pharmaceutical Society of Great Britain, and of the American Pharmaceutical Association.

The admixture of the rhizomes and roots of *Veratrum album*, L. with the similar parts of *Valeriana officinalis*, L., is so far as I know, entirely without precedent, but having recently detected such an admixture, I take the first opportunity afforded me of bringing it under the notice of a meeting of the Pharmaceutical Society, in order to guard, as far as possible, against the recurrence of this most serious adulteration.

The history of the present case is as follows:—A short time since I received a letter from an old pupil, who is now a pharmaceutical chemist in a large manufacturing town in this country, enclosing a sample of a drug picked out of a parcel sold to him as valerian root. In that letter he says, "I sold to a retail customer the other day a small quantity of valerian root. An infusion was made from it and intense sickness was caused by all who took it; the sickness was so violent that a doctor was sent for, the parties suspecting they were poisoned. They recovered in a few days but remained very weak and sore for several days from its effects." He adds, "Will you kindly examine it and inform me if it is genuine valerian root, as I cannot account for the extraordinary effect it produced?"

Before even reading the letter thus describing the effects of this specimen of valerian root, I at once saw that the sample sent had been derived from a species of *Veratrum*, and immediately wrote to my correspondent to that effect, and to say that the admixture was a most serious one, and that, as its use might be attended with fatal results, I requested him to send the remainder of the specimen to me, and to communicate at once with the house from whom he had received it. On receipt of my letter he telegraphed to the house from whence it had been obtained to stop the sale and get back what was sold of the valerian root, and forwarded as I had requested the remainder of his parcel to me. In this way all further injurious consequences were guarded against as far as was possible from this particular sample; and now, in the hope of preventing any future accidents from such a very serious admixture, I call attention to the principal distinctive characters between the two drugs as exhibited in the present specimen.

In the first place the veratrum rhizomes are either crowned by a conical bud of unexpanded leaves, or by the fibrous remains of leaves which they once bore. These leaves, at first sight, bear some faint resemblance to those found at the end of the creeping shoots or stolons which are developed from the rootstock of the true valerian plant, and by which that plant is propagated; but the leaves in the latter plant are opposite to each other, and overlap at their base, while those of veratrum form concentric sheaths, which are arranged one within the other. Moreover, in commercial specimens of valerian root, such stolons are rarely or ever found. The presence and arrangement of these leaves ought therefore, at once, to lead to the detection of white hellebore rhizomes when mixed with those of valerian.

Secondly, the white hellebore rhizomes are much larger than those of the valerian, and also entire, whereas the valerian are commonly more or less cut, as in the specimen now under examination. The rhizomes of veratrum are also of a darker colour, and when of any length marked below with the pits and scars of old roots.

Thirdly, a transverse section of white hellebore rhizome presents a large central woody or spongy portion of a whitish or pale buff colour, which is separated by a fine wavy-crenate ring from an outer broad white part which is coated by a thin dark brown or blackish bark-like portion. The appearance of this transverse section, particularly that of the undulating ring, is very different from a similar section of valerian rhizome, which although whitish at first, presents, in commercial specimens, a dark brown firm and horny central portion, separated by a dark interrupted cambial zone from the cortical part, which is also of a brown colour. A vertical section of veratrum rhizome is also very characteristic, and more especially so, from presenting a fine dark wavy conically arranged line running nearly throughout its whole length, and thus separating the outer from its central portion. No such wavy line is seen in valerian rhizome.

Fourthly, the roots of veratrum which arise from the upper part of the rhizome only, are of a paler colour externally than those of valerian rhizome; they are also commonly larger and more shrivelled.

Fifthly, the taste of veratrum rhizome and roots is at first sweet, then bitter, acrid, and somewhat numbing; while the similar parts of valerian have no acridity, but are evidently aromatic and somewhat bitter.

Sixthly, the veratrum in itself has no marked odour, and although by its admixture with valerian root it has acquired the peculiar odour of that drug, it is feeble when compared with valerian itself. The veratrum rhizome also excites sneezing when cut or bruised, as I found by its action on myself in making sections to examine its structure.

Such are the principal distinctive characters of white hellebore and valerian rhizomes and roots. It would not be difficult to mention several others derived from their microscopical and chemical examinations, but my object in the present paper is to allude only to a few characters by which, on the most general examination, the two drugs may be at once distinguished, and in this way, to guard against any possibility of their being confounded together. There is, however, one chemical distinctive character, which is so marked, and at the same time so simple and readily observed, that it will be useful to notice it. This is derived from the application of sulphuric acid to a transverse or vertical section of the two rhizomes. Thus if it be added to a section of white hellebore a deep orange-yellowish-red colour is at once produced from its action on the contained alkaloids, which soon changes to a dark blood-red; but its application to a section of valerian is simply to heighten the natural colour of that drug.

The sample of valerian root which forms the subject of this paper when it reached me weighed exactly forty-two ounces, of which thirty-four ounces were true valerian, and eight ounces white hellebore rhizome, so that the serious nature of the admixture

* Read at an Evening Meeting of the Pharmaceutical Society of Great Britain, February 7, 1877.

may be at once seen. In the sample I also found a few pieces of veratrum rhizome without any trace of leaves, but with the roots still attached. Such pieces have, of course, a much greater resemblance to valerian root, but they can be readily distinguished with ordinary care, by the different appearances presented on making a transverse or vertical section of the two rhizomes, and by the action of sulphuric acid.

And now I must say a few words with regard to the botanical and geographical sources of the veratrum rhizome thus found mixed with valerian root, and the probable way in which such a mixture occurred. It would be difficult, if not impossible, from the specimen before us, to pronounce with absolute certainty as to the species from which it had been derived, but I have little doubt that it was from some form of *Veratrum album*, L., and that both it and the valerian rhizome were gathered together, and probably in ignorance of their different natures, on the continent of Europe, and imported into this country in this mixed condition. But since I first formed this opinion, my correspondent from whom the specimen was derived informs me, that the explanation now given to him is, "that the bales of valerian and veratrum had been broken at the docks—the contents scattered about and carelessly picked up and stuffed in any way." I can scarcely believe in such gross carelessness; and moreover an additional argument in favour of the cause of the mixture I have suggested, is derived from the fact that the veratrum rhizome is not imported in the state in which it is found in the present specimen, but commonly without attached fibre, and with but faint traces of leaves in the form of concentric sheaths at the apex. It is true that pieces of rhizome may be sometimes found in bales of white hellebore which present all the appearances I have described as being found in the present specimen; but so far as I know, bales of such rhizomes are rarely or ever found in commerce. But whatever conclusion we may form as to the cause of the mixture of the two drugs, it seems quite clear that it was accidental, for although foreign valerian root is higher in price than that of white hellebore, the difference is not more than two pence in the pound; so that there could scarcely be any temptation on this ground for the addition of white hellebore rhizomes to those of the valerian.

There are two practical conclusions which I think we may draw from the present inquiry. First, the pressing necessity of an examination by a competent person, appointed for that purpose, of imported drugs, more especially when these are plants or parts of plants, such as roots, rhizomes, leaves, etc., for every one who is familiar with the bad condition in which such drugs now frequently arrive in this country, and the accidental and intentional adulterations, to which they are liable, must see the importance of this; and secondly, we may learn that even we cannot be too careful in examining the drugs in our home stores and pharmacies, for so far as the specimen which forms the subject of the present paper is concerned, it has been traced through three houses, and its sophistication passed unnoticed, until the accident occurred from its use which caused it to be submitted to a careful examination, and its nature detected.

[*The discussion on this paper is printed at p.* 665.]

THE COLOURING MATTER OF THE PETALS OF ROSA GALLICA.*

BY HAROLD SENIER.

The red colouring matters which occur in the petals of flowers have been studied by many chemists, but no one, so far as I am aware, has examined specially the red colouring principle of rose petals. The researches to which I refer are those of Marquart, Filhol, Fremy, and Elsner, and while they have served to guide my steps, I have in many cases found them inaccurate as applied to the colouring principle of rose petals specially.

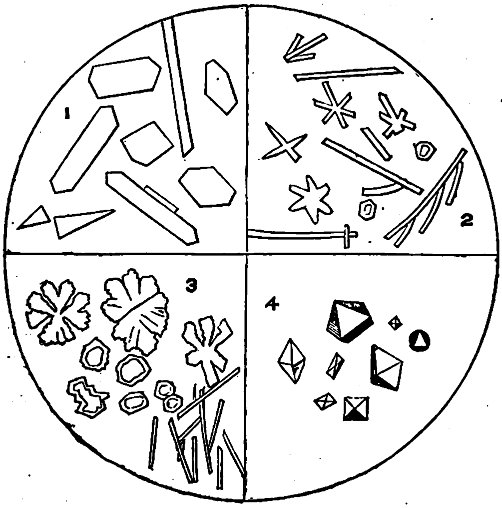
Extraction.—The dried petals of commerce were first digested with ether, and the ethereal solution removed by filtration. By this treatment quercitrin —the yellow colouring matter—and solid fat are removed (Filhol). Experiments were next made to ascertain the relative value, as solvents of the colouring matter, of chloroform water and alcohol. No colouring matter was dissolved by the chloroform; hot water dissolved it freely, but dissolved also much albuminous matter. Alcohol was found decidedly the best, yielding a solution comparatively free from other substances. But while the solution in water is of a bright red colour, that in alcohol is at first colourless—due most likely to some reducing action of the alcohol—but acquires in time a red tint, which brightens with age. From this alcoholic solution the colouring matter was precipitated in a green amorphous state by acetate of lead. This precipitate after washing and drying (100° C.), was treated in two ways:—Firstly, the precipitate suspended in rectified spirit was decomposed by sulphuretted hydrogen, and the mixture filtered (Elsner). Secondly, the precipitate suspended in rectified spirit was decomposed by dilute sulphuric acid, taking care to have the precipitate in excess, and the mixture filtered. Both these latter solutions have a bright red colour. The solution obtained by means of dilute sulphuric acid was found to be the purer, though most of the reactions detailed below may be obtained from either or even from the original alcoholic solution.

Action of Reagents.—Dilute *acids* deepen the colour, but concentrated they decompose it, concentrated nitric yielding a yellow solution. Alkalies change the colour from bright red to a deep red with a bright green fluorescence, and when added in excess give a yellow solution. A drop of solution of *soda* and a drop of the solution of colouring matter, placed on a glass slide and slowly evaporated by a gentle heat, yield under the microscope a mass of well-defined crystals. The drawing (fig. 1) represents their form. *Potash* yields crystals when treated in the same manner (fig. 2). *Ammonia* itself does not give crystals, but combined with soda gives the forms shown in (fig. 3). With potash, ammonia gives with the colouring matter perfect octahedra (fig. 4). These crystals under the microscope, if treated with an acid, yield the colouring matter in the red form, which evidently arises from the crystals not from the solution, thus showing that they are actual combinations of the colouring matter. With considerable difficulty I succeeded in preparing and separating a specimen of the ammonio-potassium salt in octahedra of comparatively large size.

* Read at an Evening Meeting of the Pharmaceutical Society, February 7, 1877.

These answer to the characters already described, and to those also of potassium and ammonium.

Alkaline carbonates act in the same manner as alkalies, except that the change of colour is accompanied with effervescence. *Chlorine* entirely destroys



1. Sodium salt. 2. Potassium salt.
3. Ammonio-sodium salt. 4. Ammonio-potassium salt.

the red colour, leaving a yellow solution. *Sulphuretted hydrogen* changes the red to brown, but so far as I have been able to determine, does not alter the chemical character of the solution. *Stannic chloride* changes the red to a beautiful dark magenta colour. On boiling with *metallic mercury* the red colour is changed to a dark violet or purple.

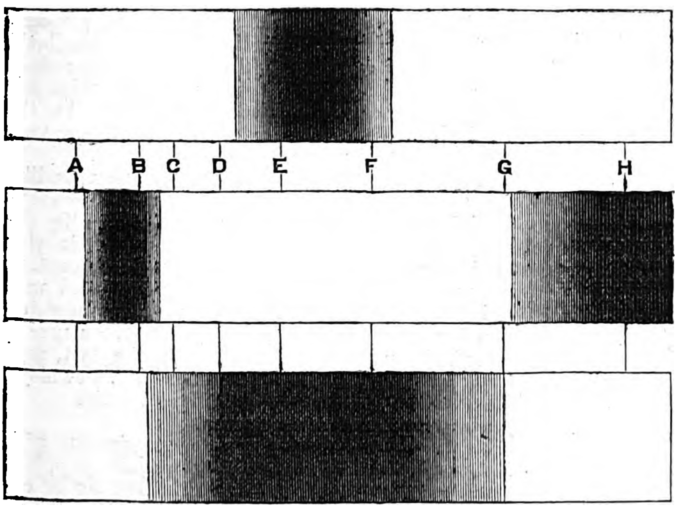


FIG. 5.

FIG. 6.

FIG. 7.

Mercuric nitrate and *chloride* both give a slight white or pinkish precipitate, soluble in water. *Hydrate of barium* yields a yellowish green precipitate, as does also *hydrate of calcium*, both becoming brown when deprived of moisture. No precipitates are given by *chloride of platinum*, *nitrate of silver*, or the usual alkaloidal reagents except very slight ones by *iodohydrargyrate* and *trinitrophenic acid*.

Carbonic acid does not redden the colourless or green modification, but though possessing this property, esteemed in cochineal, it has not proved practically useful in my hands as an indicator in alkalimetry.

Peroxide of hydrogen appeared to give no reaction. *Sulphurous acid* leaves the colour of a brown shade. To *test paper* all the solutions have an acid reaction.

Neutral and basic *acetates of lead* give precipitates of a colour varying from a green to a bluish-green. These precipitates decomposed by sulphuric acid yield the colouring matter to the solution, as already mentioned, and deposit sulphate of lead. The action of reagents leads me to conclude that the colouring matter is an acid, and that as such it forms salts—the crystals and precipitates described.

Analysis of Lead Salt.—A specimen of the lead salt, previously dried over sulphuric acid, was submitted to ultimate analysis, with the following results:—

I. 1·219 grams of lead salt gave 0·623 of sulphate of lead. 0·714 of lead salt gave 0·159 of water, and 0·559 of carbonic anhydride. 0·358 of lead salt, for nitrogen, gave 0·011 of platinum.

II. 1·261 grams of lead salt gave 0·647 of sulphate of lead. 0·545 gave 0·1215 of water, and 0.4341 of carbonic anhydride. 0·902 of lead salt, for nitrogen, gave 0·016 of platinum.

III. 0·169 gram of lead salt gave 0·088 of sulphate of lead. 0·2491 gave 0·0545 of water, and 0·191 of carbonic anhydride. Nitrogen was not estimated a third time.

In percentages,

	I	II	III	Average.
Pb . . .	34·94	35·05	35·50	35·16
C . . .	21·34	21·72	20·91	21·32
H . . .	2·48	2·48	2·43	2·46
N . . .	·43	·25		·34
O . . .				40·72

These figures (omitting the nitrogen which is probably an impurity) correspond to some such formula as the following:—

$Pb_2C_{21}H_{29}O_{30}$, thus—

2 Pb	.	414	35·23
21 C	.	252	21·45
29 H	.	29	2·47
30 O	.	480	40·85
		1175	100·00

Action upon Light.—The absorption action of the solution of colouring matter was examined by a two prism spectroscope. The solution used was made by decomposing about half a gram of the lead salt, suspended in rectified spirit, with sulphuric acid, until upon gently warming for some time only a small quantity of undecomposed lead salt remained. This solution was then filtered, and diluted with spirit to about six ounces.

Through a stratum of about half an inch of this solution—previously treated with reagents—light was passed. The stratum of solution was then diluted with rectified spirit until the bands became distinct, one part of solution to three of spirit being about the proportion required. The most interesting of the spectra observed are illustrated in figures 5, 6, and 7. Figure 5 represents the absorption spectrum of the solution rendered acid by sulphuric acid, figure 6 that of the solution made alkaline by ammonia, and figure 7 the spectrum of the solution treated with stannic chloride.

In conclusion, I have to thank Mr. Saunders for permitting me to work out most of this research in the laboratories of Messrs. Godfrey and Cooke, and my brother Dr. A. Senier, who by permission of Professor Attfield made the necessary combustions in the laboratories of the Pharmaceutical Society.

[*The discussion on this paper is printed at p.* 665].

NOTE ON THE ACTION OF DILUTE NITRIC ACID ON BRUCIA.*

BY W. A. SHENSTONE, F.C.S.

In an abstract of a paper by Professor Sonnenschein, published in the *Pharmaceutical Journal*, (No. 272, 3rd series) it was stated that by warming with dilute nitric acid, brucia yields strychnia, accompanied by a yellow resin, etc., carbonic acid gas being at the same time given off. In April, 1876 (*Pharmaceutical Journal*, No. 304), Mr. Cownley gave an account of a number of experiments made by himself on the subject, using pure brucia and nitric acid of various strengths. In no case was he able to obtain evidence of the production of strychnia. As Sonnenschein obtained strychnia in sufficient quantity to prepare its hydrochlorate and determine the chlorine in it, these statements are, I think, sufficiently opposed to make further experiments on the subject interesting, and I have therefore lately paid some attention to the subject.

1. My first experiments were made with commercial brucia of apparently good quality and of known source.

(*a*) About ·5 gram of brucia was heated in a water-bath with a mixture of 1 part of acid. nitric., B.P. and 9 parts of water, then rendered alkaline with potassium hydrate and shaken with chloroform, the chloroform solution drawn off by means of a separating funnel and evaporated; the residue gave full indications of strychnia with sulphuric acid and bichromate of potassium.

(*b*) A similar experiment to (*a*), but the solution of brucia in nitric acid was evaporated on a water-bath, the acid being thus gradually concentrated, this was in effect using a stronger acid. Only slight evidence of strychnia was obtained on examining the residue from chloroform.

(*c*) Also a similar experiment to (*a*), but using nitric acid half the strength of the acid employed in that case. Crystals were obtained in some quantity which gave the reaction of strychnia.

In all these experiments carbon dioxide was given off in considerable quantity, and the strychnia was accompanied by a small amount of a yellow resinous substance.

2. The following experiments were made with brucia specially prepared for me by Mr. John Williams, whom I take this opportunity of thanking for his assistance:—

(*a*) ·5 gram of brucia was warmed with several times its weight of nitric acid (17·5 per cent. HNO_3) as long as carbon dioxide escaped, then rendered alkaline with potassium hydrate, shaken with chloroform, the chloroform solution drawn off and evaporated, and the residue examined for strychnia. Six such experiments were made; in each case the residue was a yellow resinous substance, and in only two cases could strychnia be found in it, and then only after heating for some hours with strong sulphuric acid to destroy the resinous body.

(*b*) Another series of six experiments, using the same brucia as in (*a*), and nitric acid containing only 5·0 per cent. of HNO_3; in some cases heat was applied by a water-bath till escape of carbon dioxide ceased; in others care was taken to prevent any evolution of gas. The acid liquid was rendered alkaline with potassium hydrate, and treated with chloroform. On evaporating the chloroform a residue was obtained, which, after heating on a water-bath with strong sulphuric acid for some hours, diluting with water, adding excess of alkali, and agitation with and subsequent evaporation of chloroform, gave a small quantity of pale yellow residue that showed the strychnia reaction freely in every case.

3. Some of the brucia used for experiment No. 2 was dissolved in acetic acid and partially precipitated by potassium hydrate, the precipitate washed and dried, and two portions of ·5 gram each were treated respectively with nitric acid containing 17·5 and 5·0 per cent. of HNO_3, and after addition of alkali to the acid solution, strychnia was searched for by the same process as before, especial care being taken in heating with sulphuric acid to destroy the accompanying resin, as only a small amount of strychnia was likely to be present. The presence of strychnia was established in each case, but evidently in reduced quantity, the best reaction being obtained from the product of the 5 per cent. acid.

4. Brucia purified by myself, by a process described later on, was taken as before in quantities of ·5 gram, and heated on a water-bath with the five per cent. nitric acid so long as carbon dioxide escaped, the liquid alkalized, and exhausted with chloroform, the residue from evaporating the chloroform charred with sulphuric acid, and examined for strychnia by the usual plan. In one case a most doubtful indication, in the other three none at all, was obtained.

It will be seen that the above experiments, like Mr. Cownley's, fail to confirm Professor Sonnenschein's results, as the strychnia found steadily decreased with the increased care taken in purifying the brucia. I was not, like Mr. Cownley, fortunate in the purity of the brucia I first experimented with, and from the trouble I experienced in preparing pure brucia, I feel some curiosity as to the source of his alkaloid; but I do not regret the fact, as I think it has enabled me to confirm Mr. Cownley's observations by a somewhat different series of experiments to those made by him.

It will be observed that the experiments with 17·5 per cent. nitric acid do not give quite accordant results, and that even in one of the last set of experiments a reaction was obtained which may have been due to the presence of a trace of strychnia in the brucia; this led me to perform the following experiments, in order to ascertain whether a small quantity of strychnia in brucia may not be destroyed by heating with even very dilute nitric acid, in which case my own purified brucia may only have been so far free that the small quantity remaining is destroyed in searching for it.

* Read at an Evening Meeting of the Pharmaceutical Society, February 7, 1877.

·5 gram brucia adulterated with ·1 per cent. of strychnia was digested as before with 5 per cent. solution of nitric acid, till the colour of the liquid was pale yellow, and crystals of cacotheline were deposited; the liquid was then examined as before for strychnia, but no evidence of its presence was obtained. A second and similar experiment on impure brucia gave a like result. When an acid containing only 1 per cent. HNO_3 was used, the brucia was very slowly attacked by it, and I did not, therefore, attempt to use a weaker acid.

The fact of one's not finding strychnia in a specimen of brucia, by acting on it with dilute nitric acid, etc., is not therefore evidence of its absolute purity, as even a very dilute acid destroys small quantities. whilst as seen by experiments described under No. 1 (*b*) (*c*), and No. 2 (*a*) (*b*), a stronger acid will destroy a comparatively considerable quantity.

After completing the above experiments, it occurred to me to ascertain the quantity of strychnia in the sample of commercial brucia used in the first set of experiments. By treating with five per cent. nitric acid, alkalizing the solution, and extracting with a small quantity of chloroform, I obtained nearly pure strychnia, in amount corresponding to rather more than 1 per cent., only one agitation with chloroform was used, as my supply was exhausted, and considering this and the destructive action of the nitric acid, it is probable that the actual percentage was somewhat higher. Now as one writer, Andral, estimates the activity of brucia as only one twenty-fourth that of strychnia, this seems to me rather a high percentage of such an active impurity, and I therefore add to my note some details as to the method I employed in purifying my brucia. Possibly it is already known, but I have not met with it before.

The process depends upon the fact that strychnia precipitates brucia from its salts, and consists in partially precipitating the brucia from one of its salts with an alkali, standing aside for a few hours, collecting, washing, and redissolving the precipitate in a dilute acid, then again partially precipitating, etc. I found that my brucia gave no indication of strychnia after four precipitations. The cost of this purification need be but slight, as the unprecipitated brucia can be recovered.

In conclusion, I would express my thanks to Professor Attfield for kindly permitting me to do a portion of this and other work in the Pharmaceutical Society's laboratories during a recent vacation.

[*The discussion on this paper is printed at p.* 666].

THE PHARMACOPŒIA TEST OF QUININE SULPHATE.*

BY B. H. PAUL, PH.D.

It has long been my opinion that in using ether as a test for the purity of sulphate of quinine there is great liability of overlooking the presence of a very considerable amount of cinchonidine. Thus, for instance, the Pharmacopœia test is based upon the relative solubility of quinine and cinchonidine in ether. Quinine dissolves in less than its own weight of ether, forming a thick sirupy solution from which no kind of crystallization can be obtained, even when it has quite dried up. On the other hand, cinchonidine dissolves only sparingly in ether, requiring, according to different statements, from 100 to 150 times its weight.

The proportion of ether indicated in the Pharmacopœia is half a fluid ounce, or about 15 cub. cent. to ten grains of the quinine sulphate, and the absence of any separation of alkaloid crystals after the addition of ammonia, is stated to be evidence of purity. I do not find this to be the case.

Upon mixing one decigram of cinchonidine sulphate with about two cubic centimetres of ether, and adding ammonia sufficient to separate the base, the presence of the insoluble alkaloid becomes sufficiently distinct.

But when the same quantity of cinchonidine salt is mixed with a large proportion of quinine, the result is different, and it appears that the presence of quinine increases the solubility of cinchonidine in ether, or at any rate prevents the latter from separating in a crystalline state.

As to the Pharmacopœia test for detecting sulphate of cinchonidine, I have applied it to sulphate of quinine, which I have, by other means, ascertained to contain ten per cent. of sulphate of cinchonidine, but the mixture remained perfectly limpid, and any one applyng the test would say that the salt was absolutely pure. I have come to the conclusion in the course of repeated experiments in testing quinine that the limit within which cinchonidine cannot be detected in quinine is very much higher than is commonly supposed. I believe that in some books it is stated to be one half per cent. of cinchonidine in sulphate of quinine. Others put the limit of detection somewhere about two or three per cent.; but I am more inclined to think that ten per cent. is the limit, and that when there is ten per cent. or a little less there is not obtained, as a matter of certainty, any indication at all of the presence of cinchonidine. I mentioned that conclusion to a friend who was practically engaged in the manufacture of quinine, and he differed from me very decidedly. He was of opinion that the limit of detection was somewhere about two or three per cent., or perhaps less, and I put the matter on one side. But it so happens that my attention has lately been drawn to the question of purity of samples of quinine, and I have gone into it very carefully, and made a number of tests with different proportions of sulphate of quinine and sulphate of cinchonidine, of the purity of which I was perfectly certain. Those who are in the habit of testing quinine will, no doubt, have observed that there is a peculiar behaviour presented by the alcaloid, namely, that with ether it sometimes gelatinizes, and it is then difficult to determine whether the appearance it presents is due merely to bubbles of air or to crystals. A mixture consisting of half a gram of sulphate of quinine and five centigrams of sulphate of cinchonidine does not show a particle of crystallization. If gelatinization takes place, the little globules of air or liquid may look like crystals; but with a sufficient proportion of ether, mixtures of ten per cent. remain perfectly liquid. If the ether be evaporated off so as to leave the liquid quite sirupy, but still there is no crystallization.

In applying the Pharmacopœia test, although there would be nothing strictly wrong in using the proportions indicated in the Pharmacopœia—half a fluid ounce of ether to ten grains of the sulphate to be examined;

* Read at an Evening Meeting of the Pharmaceutical Society, February 7, 1877.

this is very much in excess of what is needed, and any one exercising his judgment would never use so much ether as is there directed. The solubility of cinchonidine in ether is so considerable, that a large quantity would pass unnoticed in that way. I have prepared a number of samples containing different proportions of quinine and cinchonidine, varying from seven tenths of a gram of quinine, and three tenths of a gram of cinchonidine, that is to say, a thirty per cent. mixture, and tested by the Pharmacopœia quantities even this would pass as being pure. A ten per cent. mixture of course passes. But even with much smaller quantities of ether it is impossible to rely on its use.

The plan that I have adopted for detecting the presence of cinchonidine has been that of fractional crystallization, and I find that it gives a very speedy indication whether there is any cinchonidine present or not. The operation is an exceedingly simple one. You take a small basin, and about thirty grains of the sulphate to be tested, add a fluid ounce and a half of water, and boil until the salt is nearly dissolved. The water is insufficient to dissolve it entirely; but when heated up to the boiling point, the greater part of the quinine sulphate is dissolved. Upon cooling, most of the quinine is deposited, and the more soluble cinchonidine sulphate remains in solution. The liquid portion is then a saturated solution of quinine sulphate, together with any cinchonidine that may be present. By applying the test to that liquid an indication may be got of cinchonidine, if present. This is a modification of the test which has been very much used on the Continent, known as Kerner's test, and the one adopted in the German Pharmacopœia. That consists in mixing the salt with a small quantity of water in the cold, then filtering off the liquid and adding a solution of ammonia, which produces at first a precipitate of quinine; but when a certain proportion of ammonia has been added, the quinine is entirely dissolved, and the result is a clear solution. The test is an exceedingly good one, and is founded on very sound principles, which are these: The sulphate of quinine is a very sparingly soluble salt, and cinchonidine sulphate is very soluble. One requires 750 parts of water, and the other only 100; so that putting those two facts together you may get a very good indication of whether sulphate of quinine contains cinchonidine or not. However, the defect attaching to this test lies in the application. It is based upon the assumption, that if you treat a mixture consisting of a large quantity of insoluble salt with a small proportion of soluble salt, you will take out the more soluble salt and leave the other. That is not the case; but the converse is more to be relied upon. If you have a solution, at a high temperature, of a salt that is sparingly soluble with a very small proportion of one that is more soluble, the less soluble salt will separate on cooling, the more soluble one being left in solution; and that is precisely the way I make the test. If, for instance, a sample of quinine sulphate, or a mixture containing one per cent. of cinchonidine sulphate, be treated with cold water, and the solution mixed with an equal volume of solution of ammonia, of 920 gravity, the result is a perfectly clear solution. But when the same salt is treated by boiling, the difference in the result is very marked, and even when treating the cold liquid with ether, the cinchonidine will separate.

In the examination of nine samples of quinine sulphate, I have found cinchonidine present in all cases, and varying in amount from one per cent. to ten per cent.*

Between these two extremes of one per cent. and ten per cent. there is a very wide margin, and I think the circumstance that such quantities may be overlooked in testing quinine is important both to manufacturers and to pharmacists, who are liable to be placed in circumstances of difficulty on account of this impurity. In the first place, a manufacturer who produced a pure article might be prejudiced in tendering for contracts, by being placed in disadvantageous competition with other persons, who offered quinine of the character I have mentioned, containing ten per cent. of cinchonidine, a proportion according to the present prices, amounting to a difference of tenpence on the ounce, which is a large extra profit on the quinine. A manufacturer offering really pure quinine, or such as that I have mentioned containing one per cent. of cinchonidine sulphate, would be unable to compete with another offering quinine containing ten per cent. So, in like manner, dispensing druggists might purchase quinine containing that amount of sulphate of cinchonidine, and might find themselves in an awkward predicament if a public analyst were to hit on the means of detecting that adventitious substance, and apply to them the mechanism of the Adulteration Act. I thought, therefore, that it would be of interest and utility to the members of the Pharmaceutical Society, if I pointed out the necessity of pharmacists being careful in examining their quinine. The plan that I should recommend for adoption is that which I have described—taking about thirty grains and boiling it with water, allowing the mixture to cool, and testing with a solution of ammonia the clear liquid obtained after filtering.

[*The discussion on this paper is printed at p.* 667.]

TESTING OF SALICYLIC ACID FOR PURITY.†

BY H. KOLBE.

Only absolutely pure crystallized salicylic acid should be used either internally as a medicine or as a preservative for wine, beer, fruits, etc. The less pure acid, which generally has a peculiar after-taste when used continually or given in large doses, may act injuriously on the health. The prejudice against salicylic acid of physicians who have failed to obtain good results with it, is due in most cases to the pharmacist having dispensed an impure preparation—the precipitated instead of the crystallized acid. The author has met with several cases in which such an acid was used. He therefore gives the following simple method of judging of the quality of commercial salicylic acid. Dissolve a small quantity, ½ gram, in about ten times as much strong alcohol, pour the clear solution into a watch glass, and leave it to evaporate slowly at the ordinary temperature of the atmosphere. The residual salicylic acid forms around the edge of the watch glass a ring of beautiful efflorescent aggregated crystals. This efflorescent mass is pure white if the acid used be quite pure and has been recrystallized; but yellowish or yellow if the simply precipitated acid be used. If the colour be brownish or brown, the preparation, however white and pure it may appear as a powder, should be rejected as bad.

* Owing to want of space the table of analytical results must be omitted until next week.

The Pharmaceutical Journal.

SATURDAY, FEBRUARY 10, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE REGISTRAR'S STATISTICS.

THE very complete series of statistical tables which the Registrar laid before the Council in his Report last Wednesday are worthy in many respects of the attention of our readers. In the first place, they are notable as showing that although the number of persons passing the qualifying examinations during 1876 was considerably in excess of the number who passed in 1875, being 259 against 174, there has been, for the first time, a considerable decrease in the number of chemists and druggists on the Register. Of course it has been foreseen that such a decrease would take place, as time began to tell upon the large number who obtained registration without examination under the provisions of the Pharmacy Act, 1868. Last year the corner was turned, there being then a decrease of 10 upon the number of the next previous Register; but this year the decrease in the number of chemists and druggists on the Register has reached 98, the number in the Register at the time of the return being 13,178, against 13,276 at the end of 1875. The number of erasures due to authenticated deaths during 1876, namely, 182, has been very low compared with those of 1875, when they numbered 220, and, as will be seen, is far below the number of persons who have been placed on the Register by virtue of having passed their examinations. But the recent exercise by the Registrar of the power entrusted to him for the rectification of the Register, resulted in the erasure of 202 names, which will account for the considerable decrease on the gross total. To some persons who have decried the Pharmacy Act as a complete failure, we would commend as worthy of their attention, and probably unequalled in the experience of any other class of business men, the fact that in the face of an increasing population they have now just upon a hundred competitors less than at the beginning of last year.

The Register of Pharmaceutical Chemists now contains 2321 names, against 2335 in the previous year, or a decrease of 14. Here again comes into play the fact that the Register is liable to depletion by deaths of both unexamined and examined men, whilst it is only recruited from the examined class. But the decrease of pharmaceutical chemists is rather low in proportion to the gross decrease, as 14 on that Register would correspond to about 80 only on the whole Register, instead of 98. The relative proportion, therefore, of pharmaceutical chemists to the whole body of chemists and druggists is slightly higher than last year, being 17·61 per cent., against 17·59 per cent. Of course, in the relative proportion of the Major men (as well as of the Minor) to the whole body there will have been a more considerable advance, but this we shall not be in a position to state until after the issue of the Register.

We now come to discuss the number of registered chemists and druggists who are connected with the Pharmaceutical Society, either as Members or Associates. It is satisfactory to note that this is in excess of that of any former year. Although there has been a decrease in two classes, and one has remained nearly stationary, there has been an increase of 39 in the gross total, the number being now 4421. The entire strength of the Pharmaceutical Society therefore now reaches 33·55 per cent. of the whole number of chemists and druggists. The Pharmaceutical Chemist Members are fewer by 22, the cause of which has already been alluded to; but it is worthy of note that the elections and restorations are 8 in excess of the number of persons who passed the Major, this indicating that of the very small proportion of pharmaceutical chemists—only 10·75 per cent.—who had previously held aloof, some have now joined the Society. The Chemist and Druggist Members show an increase of 1; and as the number from which this class can be drawn yearly becomes less, and must eventually become extinct, probably a decrease here must be expected from this period. In the important class of Associates in Business, there has been an increase of 130, being a larger increase than in any previous year. On the other hand, there has been a decrease of 70 in Associates not in business, which perhaps may find a partial explanation in an increased tendency in examined men to embark in business on their own account. However this may be, if from the 232 persons who passed the Minor examination, and thus recruited the class from which Associates are eligible, 62 be deducted as representing those who passed the Major, and thus became ineligible as Associates, it is evident that the balance, even if they had all joined the Society, would, after allowance had been made for death, secessions, etc., have been barely sufficient to have supplied the increase (130) of Associates in Business, and that the balance of the number must have been drawn from the Associates not in business and from qualified persons who had not previously joined the Society. The number of Registered Apprentices or Students of the Society, who, of course, are not included in the Register of Chemists and Druggists, has increased from 852 to 934.

The following table therefore represents the strength of the Pharmaceutical Society relative to the Register of Chemists and Druggists :—

	1876.		1877.	
	No.	Per cent.	No.	Per cent.
Pharmaceutical Chemists, Members of the Society .	2084	89·25	2062	88·84
Other Registered Chemists and Druggists connected with the Society . . .	2299	—	2359	—
Total Number of Registered Chemists and Druggists connected with the Society	4383	33·01	4421	33·55
Registered Apprentices subscribing to the Society .	852	—	934	—

In conclusion, we would again point out the bearing that these figures have upon opinions that have been expressed more than once recently, when the strength of the Pharmaceutical Society relative to the Register has been much underestimated by various speakers and writers. On one occasion, when the rhetorical exaggeration went further than usual, and it was stated that "the Pharmaceutical Society in all these years has only brought in a tithe of the trade," we ventured to append a note pointing out that as a matter of fact, and not of opinion, one-third of all the chemists and druggists on the Register were connected with the Society. This note was stigmatized by a contemporary as "not quite relevant," as the speaker was obviously referring to chemists and druggists in business for themselves, and that therefore a deduction would have to be made from the Associates and Pharmaceutical Chemist Members. We do not know whether our contemporary had the authority of the speaker for this reading of the sentence, but unless it be assumed that the proportion in the Society of persons not in business is larger than among those on the general Register, it tells in favour of the view expressed by us. Here, fortunately, we have facts to deal with again. The number of chemists and druggists in business in Great Britain has been estimated, we have been told by a Vice-President of the Trade Association, at 8000, and probably this is near the mark. To these belong all the Chemist and Druggist Members, all the Associates in Business, and nearly all the Pharmaceutical Chemist Members. The sum, therefore, stands thus—

Pharmaceutical Chemist Members, 2062, less, say, 10 per cent., who are not in business	1856
Chemist and Druggist Members ...	839
Associates in Business	706
Total ...	3401

In proportion to 8000 this is upwards of 42 per cent. instead of 33 per cent. But can it be contended that men not in business for themselves have "obviously" no interest in the future of their calling?

In consequence of the space taken up in the present number by the reports of the Society's Meetings, we are compelled to defer the publication of several communications.

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL.

Wednesday, February 7, 1877.

MR. JOHN WILLIAMS, PRESIDENT.

MR. WILLIAM DAWSON SAVAGE, VICE-PRESIDENT.

Present—Messrs. Atherton, Atkins, Betty, Bottle, Cracknell, Frazer, Greenish, Hampson, Hanbury, Hills, Mackay, Owen, Rimmington, Robbins, Sandford, Schacht, and Shaw.

The minutes of the previous meeting were read and confirmed.

The Board of Examiners for 1877.

The Secretary read a letter from the Privy Council, approving of the appointment of the examiners made by the Council in December last.

Penalties Recovered under the Pharmacy Acts.

The Secretary also read a letter that he had received from the Treasury, stating that a deputation from the Council would be received on the subject of the application of the penalties recovered by the Society under the Pharmacy Acts, and suggesting that Monday next should be fixed for that purpose.

Retiring Members of Council.

The lot being taken in the usual manner for the seven members of Council who should retire in May, the following names were drawn :

Atherton.	Frazer.	Shaw.
Bottle.	Greenish.	Williams.
Cracknell.		

The following, who remained in by lot last year, now retire by rotation :—

Betty.	Hanbury.	Robbins.
Brown.	Rimmington.	Stacey.
Hampson.		

The following remain in office for another year :—

Atkins.	Owen.	Savage.
Hills.	Sandford.	Schacht.
Mackay.		

Elections.

MEMBERS.

Pharmaceutical Chemists.

Churchill, Walter John ....Birmingham.
Davidson, Alexander ....London.
Robinson, Thomas Dexter ......Stevington.

The name of John Cort, of 62, Liverpool Street, Salford, Manchester, was ordered to be restored to the Register of Chemists and Druggists.

Registrar's Report.

The Registrar's Annual Report, showing the present numerical strength of the Society, the comparative numerical strength for five years, the analysis of examinations, etc., was placed upon the table. It is printed on pages 658 and 659.

Reports of Committees.

Finance.

The report of this Committee was received and adopted, and various accounts ordered to be paid.

Benevolent Fund.

The report of this Committee included a recommendation of the following grants:—

£10 to the widow of a chemist and druggist having two young children dependent upon her.

£15 to a registered chemist and druggist suffering from dangerous illness.

£5 to a registered chemist and druggist, suffering from ill health.

£20 to a registered pharmaceutical chemist, who has been many years in business, but is in great misfortune owing to long illness.

£10 to a former member of the Society, aged 60. Applicant has had three previous grants of like amount.

£10 to the widow of a former member many years in business.

£10 to the widow of a late annuitant.

£10 to a registered chemist and druggist, aged 76.

Several other cases had been considered, of which some were deferred for further inquiries, and others could not be entertained.

Mr. Owen had reported that he had no opportunity of profitably applying the twenty guineas, recently placed in his hands for the purpose of ensuring the election of a child into the Orphan Asylum, and he had therefore returned the money.

Mr. Betty formally objected to one of the proposed grants, as having been recommended by the Committee on an informal application.

The President read the letter which had been received from the applicant's daughter.

Mr. Betty said he made no objection to the merits of the case, but merely as a matter of form, because he did not think the application came within the regulations. He did not wish to prevent the person referred to receiving a grant from the Society, and hoped that a few words would be introduced into the regulations which would enable such cases to be dealt with.

The President said he considered the petition originally sent in by the applicant himself, and upon which his name had been placed upon the approved list of annuitants, was quite sufficient to justify the recommendation of the grant.

The Vice-President, Mr. Owen, Mr. Sandford, and others, having expressed the same view,

The report and recommendations of the Committee were received and adopted.

Mr. Shaw moved the suspension of the standing orders in order that a motion of which he had given notice with reference to amending the regulations of the Benevolent Fund might be considered.

This was agreed to.

Mr. Shaw moved—

"That the Council adopt the Regulations of the Benevolent Fund which were recommended to the Council for adoption at its meeting in December last in the report of the Benevolent Fund Committee."

These regulations had been approved by a majority of the Benevolent Fund Committee in December last, and presented to the Council on the following day, when it was after some discussion decided to postpone the question. To this he objected, thinking it important that these amended regulations should come into operation, and he had therefore given this notice of motion, and a copy of the proposed rules had been sent to each member of the Council. He then briefly drew attention to the alterations which had been made by the committee, and moved their adoption. He proposed that the various clauses should be considered *scriatim*.

After some discussion it was decided to refer the proposed regulations for verbal revision to a small committee, consisting of Messrs. Shaw, Betty and Sandford. The report to be submitted to the Council at its next meeting.

The Secretary presented the following statement, showing the amount of temporary assistance given from the Benevolent Fund during the past year, and who were the recipients; also a table showing the number of subscribers and donors to the fund, and the amount contributed by each :—

North British Branch.

The balance sheet of the North British Branch was presented, and the sum of £100 was ordered to be handed to the Honorary Secretary for current expenses, in addition to £13 0*s.* 2*d.* balance due to him on the account rendered.

Library, Museum, and Laboratory.

The report of this Committee included the Librarian's statement of the average attendance in the Library during the previous month, viz., day 23, evening 7. Circulation of books, 73 in town, 29 in the country, to 12 places. The Committee recommended that the 'Annalen der Chemie' be subscribed for, and that Baillon's 'Dictionnaire de Botanique' and Cooke's 'Mycographia' be kept for reference only, and not circulated. They had also given instructions as to the binding of the books purchased by the Hanbury Fund.

The Curator reported the attendance in the Museum to have been, on the average, day 20, evening 4. Also that the sets of specimens for the Professors were now completed.

Professor Redwood had reported that forty-nine students were now attending his class; also that the specimens supplied him for his lectures were satisfactory.

Professor Bentley had reported that thirty-eight students were attending his course, a number lower than the average. He also had expressed his satisfaction with the specimens supplied him for lectures.

Professor Attfield had reported fifty-seven entries in the laboratory since the commencement of the session, forty-four students now being at work, and that the attendance of the Bell scholars had been regular. The number of students was rather less than at this time last year, but was about equal to the average of previous years.

The Committee had considered a proposition submitted to it by the Council with reference to retaining a portion of the fees paid by candidates for examination who did not present themselves. It recommended that candidates failing to appear should be put upon the same footing as those who failed to pass. In cases of unavoidable inability to attend the Council would of course have power to waive the payment of a further fee.

Mr. Greenish hoped it would be understood throughout the country that members might obtain illustrated works from the library, by special application to the Secretary.

Mr. Cracknell did not think it would be wise to adopt the recommendation as to the forfeiture of fees by candidates who did not present themselves. The examinations were already surrounded by difficulties, and he did not think it would be wise to increase them. There might be many reasons why a candidate did not come up which would appear valid to him, though not to the Council, and as the cases were not very numerous he should prefer to let things remain as at present.

Mr. Rimmington took the same view.

Mr. Hampson asked how many cases occurred of candidates paying their fees and not coming up for examination.

The President said there were three last time.

Mr. Hampson did not think such a small number—say twenty in the year—was sufficient to justify the introduction of such a rule.

Mr. Mackay thought the whole fee should be returned when the candidate did not attend.

Mr. Bottle said he agreed with the proposition, but did not like these continual alterations in the rules.

Mr. Mackay said some of the candidates were under the impression that having failed to pass at one examination they could present themselves at the next examination, whereas they could not come up again in less than three months. These words ought to be added to the red ink notices which were pasted on to the syllabus.

Mr. Sandford explained with reference to the proposed alterations in the regulations regarding the fees that it might affect the arrangements of the Board of Examiners. The candidates did not always give notice that they should not attend, but simply stayed away. He also pointed out that the Council would be able to remit the fees in all suitable cases. He, therefore, thought the Council might safely accept the recommendation of the Committee.

Mr. Greenish said the Committee was not at all unanimous upon this point. He did not think the cases were numerous enough to warrant any alteration in the rules.

Mr. Betty considered the most objectionable part of the resolution was the power reserved to the Council to waive the fee. The suggestion ought to be carried out thoroughly or not at all.

It was eventually decided to accept the report and recommendations, with the exception of the portion relating to the retention of the fees of candidates who did not present themselves.

The Bristol Association.

Mr. Schacht said he should shortly have to make an application on behalf of the Bristol Association for a grant towards its proposed library, and he hoped members of the Council would consider the report, which would appear in the Journal, of what the Bristol Society had done and was doing.

House.

The report of this Committee referred to the work proposed to be done in the examiners' laboratory, and other matters connected with the house. The report was received and adopted, and the work proposed was ordered to be done under the supervision of the President.

Benevolent Fund Dinner and Conversazione.

The President said it was now ten years since a dinner had been held in aid of the Benevolent Fund, when many wholesale firms subscribed, their subscriptions entitling them to vote for ten years, which had now elapsed. It was therefore suggested that it would be a very proper time to hold another dinner in aid of the Fund, but if so it was necessary to form a small committee to make the arrangements. Another question was whether the Society should hold a conversazione this year.

Mr. Shaw suggested that the conversazione should be omitted this year and the amount it would cost should be handed to the Benevolent Fund.

Mr. Mackay said he would propose that no conversazione be held, and that the annual dinner in May be in connection with the Benevolent Fund.

Mr. Atkins said he personally should regret to see the conversazione discontinued, because it was the only occasion when ladies could be present. Would it not be possible to hold it at less expense?

The President said the great objection last year was to what was considered the exorbitant price charged for refreshments, and it was suggested that no refreshments should be supplied. The objection to this was that notice had not been given, but it was quite possible to announce it in good time this year, and thus make a great saving in the cost of the conversazione.

Mr Robbins took the same view. He thought it would be a great mistake to omit the conversazione altogether, but it was quite unnecessary to provide refreshments.

The Secretary said, the Society of Arts had held a conversazione at South Kensington without supplying refreshments, and he had been informed that no complaints had been made in consequence.

Mr. Betty thought it would be better not to hold a conversazione this year, but to concentrate all their energies on making the Benevolent Fund dinner a great success.

The President supported the idea of holding a conversazione at a reduced expenditure, since it would be a great disappointment to the ladies to discontinue it. The cost of refreshments last year was upwards of £120.

Mr. Greenish said there was nothing in common between the dinner and the conversazione. They should be kept quite distinct.

Mr. Frazer advocated the conversazione in order to make the Benevolent Fund dinner a success.

It was ultimately resolved to hold a conversazione at the South Kensington Museum on the 16th of May, if permission could be obtained from the Lords of the Committee of Council on Education; and that a Committee, consisting of Messrs. Betty, Greenish, Robbins, and Sandford, be appointed to make the necessary arrangements. An instruction was given to the Committee that refreshments should not be supplied. It was also resolved that a dinner be held, in May, in aid of the Benevolent Fund, and that Messrs. Betty, Bottle, Hills, Sandford, Savage, and Williams, be the Committee to make the necessary arrangement, with power to add to their number.

Mr. Owen moved—

"That it be a recommendation to the Dinner Committee to consider the desirability of making arrangements for the attendance of ladies at the proposed Benevolent Fund Dinner."

This motion was seconded by Mr. Hampson.

The President thought the matter had better be left to the discretion of the Committee.

Law and Parliamentary.

The report of this Committee contained a statement of the progress of proceedings in several cases of alleged infringement of the Pharmacy Act. Some correspondence had taken place between the Registrar and the Secretary of the Chemists and Druggists' Trade Association, with regard to the prosecution of persons for illegal trading; letters had also been received from a chemist in the country, stating that he was being threatened with prosecution by a Medical Association for prescribing over the counter. The Committee recommended that in this case the person prosecuted should be defended, if, on inquiry, it were found to be a case of simple prescribing over the counter. Messrs. Greenish, Hampson, Hanbury, Hills, Betty, and Sandford had been appointed the Sub-Committee to consider what amendments were desirable to be made in the Pharmacy Acts should an opportunity occur.

The following is a *résumé* of the correspondence referred to above:—

"Birmingham, 27th November, 1876.

"The Secretary,
"Pharmaceutical Society of Great Britain,
"17, Bloomsbury Square, W.C.

"Sir,—On other side please find particulars of three cases of illegal trading under the Pharmacy Act. Should the Council of your Society think fit to proceed against these persons, the necessary evidence is in my possession, having personally purchased the poisons named during the last twelve days.

"I am frequently receiving letters from various parts of the country stating that unregistered men are openly dealing in Scheduled poisons. If I collect the necessary evidence to proceed in such cases, would the Council of your Society instruct their solicitor to go forward and sue for the penalties?

"Waiting your reply,
"I am, Sir, yours faithfully,
(Signed) "W. F. Haydon, Secretary."

[*Here follows a list of the cases referred to.*]

"November 28, 1876.

"The Secretary,
"Chemists and Druggists' Trade Association,
"Birmingham.

"Sir,—I am in receipt of your letter of yesterday's date, reporting three cases of infringement of the provisions of the Pharmacy Act, 1868, and will lay it before the Council at its next meeting.

"One of the persons you refer to is a registered chemist and druggist, and another has presented himself on several occasions for the Minor Examination, but hitherto without success.

"You are perhaps unaware that in cases of the sale of poisons improperly labelled, the law can be put in force by anyone, the intervention of the Registrar appointed under the Pharmacy Act not being required as is the case in prosecutions for the non-registration of the seller of poisons.

"I am, Sir, yours obediently,
(Signed) "Elias Bremridge,
"Secretary and Registrar."

[*Some further correspondence took place solely in reference to the person who was stated to be registered.*]

"December 8, 1876.

"To the Secretary,
"Chemists and Druggists' Trade Association,
"Birmingham.

"Sir,—Your letter of the 27th ultimo in reference to cases of illegal trading under the Pharmacy Act, was laid before the Council at its meeting on the 6th instant. I have to inform you, that acting under the instructions of the Council, I have communicated with Mr. [A.] in reference to his reported infringement of the provisions of the Pharmacy Act, 1868; and that the death of Mr. [B.] not having been officially notified to me, I am making inquiries as to the correctness of the report of his death. I have further to say that any evidence of infringements of the provisions of the Pharmacy Act, 1868, forwarded to me, will be submitted to the Council.

"I am, Sir, yours obediently,
(Signed) "Elias Bremridge, Registrar."

"Birmingham, 15th January, 1877.

"The Secretary,
"Pharmaceutical Society of Great Britain,
"17, Bloomsbury Square, London, W.C.

"Sir,—I have to inform you that at a meeting of the Law Committee, held on the 10th inst., a resolution was passed instructing me to apply to the Council of the Pharmaceutical Society for a definite reply to the question contained in my letter of Nov. 27, 1876, which states: 'I am frequently receiving letters from various parts of the country, stating that unregistered men are openly dealing in Scheduled poisons. If I collect the necessary evidence to proceed in such cases, would the Council of your Society instruct their solicitor to go forward and sue for the penalties?'

"The final sentence in your letter of December 8th, 1876, is not considered by the members of the Law Committee by any means a satisfactory reply to this question.

"In your letter, of the same date, you state 'that the death of Mr. B—— not having been officially notified to me, I am making inquiries as to the correctness of the report of his death.' I shall be glad to know if your inquiries have convinced you of the correctness of my information in this case, and if the Council of your Society purpose taking any steps in the matter.

"I have already collected a further amount of evidence in numbers of large towns, which evidence is waiting a satisfactory reply to the question contained in my letter, previously referred to.

"I am, Sir, yours faithfully,
(Signed) "W. F. Haydon, Secretary."

"January 16, 1877.

"The Secretary,
"Chemists and Druggists' Trade Association,
"Birmingham.

"Sir,—I have to acknowledge the receipt of yours of yesterday's date, and will lay it before the Council at its next meeting.

"I have ascertained that Mr. [B.] is dead, and I have written to Mr. [B's successor] in reference to his infringement of the provisions of the Pharmacy Act, 1868. Mr. [A.] has disposed of his business.

"Allow me to suggest the desirability of your sending me the particulars of the cases of infringement you refer to, as I believe it is not probable the Council will consent to forego the consideration of, and judgment upon, any case you may have to report.

"I am, Sir, yours obediently,
(Signed) "Elias Bremridge, Registrar."

"Birmingham, 17th Jan., 1877.

"The Secretary,

"Pharmaceutical Society of Great Britain,

"17, Bloomsbury Square, London, W.C.

"Sir,—I am in receipt of your letter of yesterday's date, and note contents.

"My instructions forbid my complying with your suggestion that I should forward you the particulars of other cases of infringements of the Pharmacy Act, 1868, of which I have collected evidence, until the Council of your Society has given the Law Committee of this Association a satisfactory reply to the question contained in my letter of Nov. 27th, 1876, referred to in my letter of the 15th inst.

"I am Sir, yours faithfully,

(Signed) "W. F. HAYDON, Secretary."

Mr. BOTTLE moved—

"That the Registrar be directed to communicate with the secretary of the Chemists and Druggists' Trade Association to the following effect: That the Council of the Pharmaceutical Society of Great Britain will not instruct any solicitor to go forward and sue for penalties under the Pharmacy Act, 1868, in cases of alleged infringement of the provisions of that Act, until evidence in support of each charge of violation of the statute has been considered and found satisfactory by the Council, when the Registrar will be duly authorized to initiate proceedings for the recovery of the penalties incurred, in accordance with the provisions of the Pharmacy Act."

He said that the correspondence above referred to had been laid before the Law and Parliamentary Committee on the previous evening, but it seemed to him that it was a question for the Council to decide, and a very important one, too. He did not see how the Council could give to the secretary of the Trade Association that which he asked, viz., a definite and satisfactory reply. There would be no difficulty in giving a definite reply, but he feared it would not be a satisfactory one. It was evident, from the whole tenor of the correspondence, that the Association was anxious to collect evidence of illegal trading all over the country, and then that the solicitor of the Society should prosecute the offenders, at the expense of the Society, the Council having no opportunity given it of passing any judgment on the cases. It seemed to him it would be unwise, impolitic, and illegal to do so. It would be most unwise for the Council to surrender its powers, which it had hitherto exercised so well. It had been frequently reported to the Council that persons were carrying on business illegally, and when the cases were investigated it turned out that some had been brought forward out of personal pique; in some cases the infringement arose from ignorance; but sometimes it was from a deliberate attempt to violate the law. In such cases the Council had always put the law in operation, with uniform success. It appeared from the correspondence, that the Trade Association was desirous of using the Society's solicitor without coming to the Council for an opinion; it altogether ignored the *Registrar*, and addressed its letters to the *Secretary* of the Society. This might seem a very small matter, but the Act of Parliament said that the penalties for certain infringements of the Pharmacy Act should be sued for by the Registrar, he being duly authorized by the Council. It would therefore be illegal to give authority to the solicitor to carry on a prosecution without the Registrar. It would also be extremely impolitic to surrender any of the powers which the Council possessed. He was very desirous of seeing this Trade Association working hand in hand with the Pharmaceutical Society, but it appeared to him that it was attempting to step into the shoes of the Society. The Council had no authority to concede to the Birmingham Association the right of prosecuting wholesale, but each case must stand on its own individual merits, and when a *primâ facia* case was made out, it was the Registrar alone who, under the directions of the Council, could prosecute.

Mr. SANDFORD seconded the motion. It was perfectly absurd to suppose that the Council would undertake to initiate legal proceedings in any case it had not considered. It was, in fact, taking away one of its principal functions. The Council had no interest in forbearing to prosecute such cases, but quite the contrary; its interest, quite as much as that of the Association, was to stop all illegal practices. He could not understand how the secretary to the Association could say that the answer sent him was not definite, the answer being that all cases which were sent to the Registrar would be submitted to the Council.

Mr. MACKAY said it was not requisite for any one holding the views enunciated by Mr. Bottle to add anything further to what had been said, but he must say when he heard last night the tenor of this correspondence he was very much astonished, because it seemed to him that if the Council were to do what had been asked by what was called the Law Committee of the Trade Association, it would be untrue not only to itself but to its constituents. The members were sent to that Council Board not as a set of stuck-up images, but as men having a certain portion of brains and with some capacity of using them. The idea that the members of the Council occupying the position they did, as representing the Pharmaceutical Society of Great Britain, should under requirement of a recently formed association be so far lost to themselves as to say unconditionally that they would prosecute in cases respecting which the Council had as yet received no information was absurd, and if acceded to, the sooner they ceased to sit there the better. It had been their practice, and he hoped would be that of their successors at the Council, before taking any step in so serious a direction as the one indicated in the correspondence, to exercise careful judgment in every individual case; and he did not think the Council would be justified in prosecuting in a single case without having fully considered its merits and all the surrounding circumstances.

Mr. FRAZER said this Association asked the Council to do what it had never done for its own Law and Parliamentary Committee. That Committee matured and brought up cases to the Council, but still the Council reserved to itself the final decisions respecting them; so that it was quite unreasonable to ask it to concede to an outside body that which it did not concede to its own Committee. In one letter the secretary of the Association stated that he had collected information, but this had been done entirely without the authority of the Council.

Mr. HAMPSON thought there was a perfect misapprehension as to the meaning of this correspondence, because he did not conceive for a moment that any association would suppose that the Pharmaceutical Society would prosecute at its bidding without full and careful inquiry into every case. He was quite sure that was not the intention, nor did he think it was intimated in the correspondence. As far as he could gather, the idea of the Association was that if it collected evidence, as it considered it was its duty to do, that that evidence when tendered to the Society would be utilized for the general good and not laid aside. He believed that nothing more was required than a mutual understanding. It was absurd to suppose that the Society would take up prosecutions indiscriminately; but, on the other hand, if the Trade Association went to the expense and trouble of collecting information, it would naturally expect that the best consideration would be given to it, and he believed an answer to that effect was all that was required.

The PRESIDENT said he thought a reply to this effect had been given.

Mr. SHAW said although he was on the executive of the Trade Association, he was not a member of the Law Committee, and must say he was astonished at the language used in the correspondence, which he thought was a mistake. He had supported the Association from the commencement; not because he thought it was in any way antagonistic to the Society, but that it might become a handmaid of it, so to speak, in restricting illegal trading, and if the desires expressed by the Chemists and Druggists' Trade Association had been received in a more friendly spirit he thought there would have been no difficulty. They all knew that when evidence was wanted they had to depend to a great extent on their own members, perhaps on the Local Secretaries, and very often unpleasant consequences ensued, and difficulties arose as to getting information at all. There was now a person ready to get up the evidence necessary to put a stop to this illegal trading; and if a reply was sent to the effect that the Council could not undertake the prosecution of any case without receiving particulars of the charge to be brought, that would be all that was necessary.

Mr. Betty said he was at a loss to see what other reply could have been made than that which had been sent by the Registrar, who had invited the Association to send up the information it had collected.

The motion was then put and carried unanimously.

The report and recommendations of the Committee were then received and adopted, with the exception of the portion which referred to the defence of a chemist threatened with prosecution by a Medical Defence Association.

Report of Board of Examiners.

The Report of the Board of Examiners on the recent Preliminary examination was read, received, and adopted.

Examined.	Passed.	Failed.

PHARMACEUTICAL MEETING.

Wednesday, February 7, 1877.

MR. JOHN WILLIAMS, PRESIDENT, IN THE CHAIR.

The minutes of the previous meeting were read and confirmed.

The following Donations to the Library and Museum were announced, and the thanks of the Society were awarded to the donors:—

Library:—'Catalogue of the Library,' 'Memoirs,' vol. 25, and 'Proceedings,' vol. 14, from the Literary and Philosophical Society of Manchester; 'Reports of the British Association for the Advancement of Science, 1872-5,' from Mr. J. Williams; 'A Manual of Cinchona Cultivation in India,' from G. King, Esq., M.B., (Author), Superintendent of the Botanic Garden, Calcutta; 'Notes on Asylums for the Insane in America,' from Dr. Bucknill, F.R.S. (Author); 'Calendar,' 1876, from the Royal College of Surgeons of England; 'Sur les Erreurs d'Interprétation ayant Rapport spécialement à l'Examen des Ecailles d'Insectes,' from Jabez Hogg, Esq. (Author); three old Catalogues of Drugs, from Mr. H. W. Pound; 'Ueber die wirksamen und einige andere Bestandtheile des Mutterkornes, von Dragendorff und Podwissotzky,' from Prof. Dragendorff; 'Rapport sur les Inconvénients que presentent les Tuyaux en Plomb pour l'Aspiration de la Bière,' from Dr. J. Morel (Rapporteur); 'Transactions,' vol. 1 to 7, from the Botanical Society of Edinburgh, per Professor Balfour.

Museum.—Specimens of the roots and leaves of *Gymnema sylvestre;* of the roots of *Euphorbia neriifolia, Clerodendron serratum, Nerium odorum, Zingiber macrostachys, Bryonia epigœa, Vitis latifolia, Abrus precatorius, Melia Azedarach, Azadirachta indica, Cocculus villosus;* of the barks of *Cinnamomum Tamala, Psidium sp., Alstonia scholaris, Casuarina muricata, Symplocos racemosa, Adansonia digitata, Myrica sapida, Holarrhœna antidysenterica, Calosanthes indica, Syzigium Jambolanum, Povetta indica, Michelia Champaca, Cordia angustfolia;* of the seeds of *Lathyrus sativus, Calophyllum inophyllum, Jatropha glandulifera, Convolvulus sp.* (Huban nil); of the leaves of *Cratæva religiosa, Cassia alata, Cassia obovata, Lawsonia alba, Rhinacanthus communis;* of the plants of *Cocculus villosus, Hydrocotyle asiatica, Cuscuta reflexa, Polanisia icosandra, Aristolochia brateata, Lobelia nicotianæfolia, Peganum Harmala, Pogostemon purpuricaulis, Eclipta prostrata;* of the fruits of *Bryonia cacuminosa, Randia dumetorum, Trichosanthes palmata, Xanthoxylon triphyllum;* of the gum resin of *Boswellia serrata, Canara Gamboge, Kuteera gum, Cochlospermum Gossypium;* of *Chaulmoogra oil (Gynocardia odorata)*, from Dr. Dymock, Bombay.

Specimens of the following Cinchona barks from Mr. J. E. Howard, F.R.S. *Cinchona Uritusinga, C. Pitayensis, C. lancifolia,* two specimens; *C. rotundfolia, C. subcordia, C. officinialis,* var. *colorada* and *lutea*; *C. Chahuarguera, C. pubescens,* var. *purpurea; C. ovata,* var. *vulgaris, C. Condaminea, C. viridiflora, C. Calisaya,* two specimens; *C. macrocalyx, C. villosa, C. lucumæfolia, C. lanceolata, C. Peruviana* and *C. micrantha; C. cordifolia;* also two spurious Cinchona barks, viz.: *Stenostomum acutatum,* and *Cascarilla magnifolia.*

Specimens of fresh Coca leaves from Mr. Charles Thomas; specimen of Nataloin from Mr. W. H. Pound; specimen of rare ferns from the Island of Ascension, and of the ingredients of a Chinese purgative prescription from Mr. Oswald A. Reade; of Valoura, from Mr. Ballchin; of Helmick's Damiana, from Professor Bedford, New York; of *Xanthium spinosum,* from Dr. Dyce Duckworth; of rhubarb, from *Rheum officinale* grown in England, from Mr. Rufus Usher; of hydrate of chlorine, from Dr. Senier; of crystallized mercuric chloride, from Mr. Bevan; of chrysophanic acid prepared by sublimation, from Mr. A. W. Postans.

In reply to an inquiry by the President concerning some of the donations to the Museum, Mr. Holmes said that the specimens of Indian drugs were presented by Dr. Dymock in illustration of recent papers in the *Pharmaceutical Journal*; that the cinchona barks presented by Mr. Howard were of considerable historical interest, one of them being the kind of bark which, according to tradition, cured the Countess of Chinchon, from whom the bark received its name; another being some of the first *C. lancifolia* imported into this country; and another, a sample of a highly esteemed bark, presented some years ago to the Pope by the people of New Granada; that the Coca leaves were freshly dried just before Mr. Thomas brought them from America, and that that gentleman informed him that Coca leaves were well known to lose their properties if exposed to air and light, even for a week. He (Mr. Holmes) thought it quite possible that, like coffee, Coca might owe its peculiar properties in some degree to a volatile oil, and that the want of success in this country in producing symptoms described by a few observers might perhaps be due to the difficulty in obtaining the drug in good condition. He also called attention to a sample of aconite from Japan which appeared in the London market last month, and which was very superior in appearance, soundness, and freedom from admixture, to that imported from Germany. He added, that good aconite root was at present a desideratum in the market, and if this Japanese kind proved to contain the same aconitine as *A. Napellus*, it would form a valuable and saleable article. Dr. Paul had undertaken to examine the root, and report upon the alkaloid contained in it.

At the invitation of the President, Mr. Postans, who exhibited a specimen of chrysophanic acid, remarked, with reference to the preparation of chrysophanic acid by sublimation, that it was stated in 'Watts' Dictionary' that in this process the acid was partly carbonized. He had verified tho fact by experiment, and it occurred to him that it would be important to know whether in this form any other change had taken place. The sublimed acid had a different appearance to that prepared by crystallization from benzol. As Professor Attfield had investigated this matter, he (Mr. Postans) hoped that he would favour the meeting with his opinion as to whether any special change had taken place in the acid.

Professor ATTFIELD said that no doubt chrysophanic acid did decompose when subjected to heat; but the proportion in which that decomposition took place depended a great deal upon the manner in which the acid was heated. He had sublimed chrysophanic acid in various ways; but he thought that when it was sublimed on a small scale, and in such a manner that the vapour was condensed on a cool surface as soon as it was produced, there was very little decomposition. He was not certain as to the proportion, but he should think that if ten grains were sublimed, less than one grain would be decomposed. If a large quantity was sublimed, and the vapour had to go any distance, obviously a vast amount of heat must be employed, and a great deal of the chrysophanic acid would be heated over and over again, and, no doubt, during prolonged exposure to a high temperature a large proportion would be decomposed. He did not think that there was any alteration in the portion which was sublimed.

The PRESIDENT said that this was a subject which was attracting a great deal of attention. It was evident that this sublimed chrysophanic acid was quite different from that produced by the ordinary means, namely, by crystallization from benzol or from alcohol, and it was very interesting to note whether any alteration had occured in its nature as well as in its appearance. It was known that salicylic acid, when sublimed, was partially decomposed, and the same thing might occur with regard to chrysophanic acid. So very little was known of these bodies that they were very thankful for any information on the subject.

A vote of thanks was passed to Mr. Howard and other gentlemen who had contributed the specimens.

A paper was then read on—

THE ADMIXTURE OF VERATRUM WITH VALERIAN ROOT.

BY PROFESSOR BENTLEY.

The paper is printed on p. 649, and gave rise to the following discussion:—

The PRESIDENT, in thanking Professor Bentley for his paper, said that this was a most important subject; and the paper proved how essential education was to the pharmacist. Without education he were at the mercy of accidents, and, perhaps fraud. The present instance was probably the rusult of carlessness; but it was most important that pharmacists should be able to distinguish the true from the false drug as it came to them. These drugs were so much alike that many pharmacists would possibly have found the difficulty of distinguishing between them a very considerable one. They were, therefore, much obliged to Professor Bentley for having pointed out to them the way in which this might be done.

Professor BENTLEY said that there was another important deduction to be made from the present case as well as the question of education. It was the state in which drugs came into this country, especially from certain parts of the Continent. One of his objects in bringing the paper before the Pharmaceutical Society was to call prominent attention to this. It was constantly the case that drugs of powerful action came into the docks much damaged, and adulterated in various ways; and he hoped that the time was not far distant when there would be a properly qualified inspector of drugs, whose duty it would be to take care that these damaged and adulterated articles should not be thrown broadcast over the country.

Mr. HOLMES said that it was his experience that drugs which came from the Continent, especially from Germany, contained a larger proportion of admixture than any others. It was difficult to say whether this arose from carelessness, or was absolute adulteration. It was needful to know the value of the drugs in the country from which they came, and the proportion in which they appeared to be mixed. A sample of arnica, which he had met with, consisted in a very large proportion of some cheaper root; and he had lately seen aconite adulterated with a root which was used in the country from which the aconite came.

Mr. GREENISH said that he would take this opportunity of again mentioning the value of the microscope in materia medica. If a student took the valerian root and the rootlet, and made sections of each of them, and again made sections of the veratrum, he could not possibly fail to detect the admixture.

Mr. HALL said that there was a practice in vogue at the docks, which merchants very much objected to, called "bulking," and it was possible that in the present instance a consignment of roots was made, and the usual system of bulking was followed so as to make the parcels of equal value. It was a subject often raised at public sales that parcels should be sold *in naturâ*, that was, in the state in which they arrived in this country; and it might now be seen in the catalogues of sales that parcels were sold worked or unworked. The "working" at the docks was conducted by men who were ignorant of the nature of the substances with which they had to deal, and the admixture might have occurred in that way.

Mr. ATKINS said that reference had been made almost entirely to imported valerian. He had heard no reference as yet to the fact that a large proportion of valerian was obtained in this country. It might be interesting to know that in the centre where he resided, a larger proportion of valerian had been collected for pharmacy and other purposes than in almost any other part. There was an extremely interesting portion of England, which was gradually disappearing, called Cranbourne Chase; and the amount of valerian gathered in that district, some thirty years ago, amounted to tons annually. When they considered that that product was gathered largely by children and by the poor, they could not be surprised at some amount of partial and unconscious admixture. This trade was one which was gradually disappearing in consequence of various causes.

Professor BENTLEY wished to mention that valerian root came from three sources. First of all, there was the English valerian, chiefly cultivated in Derbyshire, and in this he had never seen any serious adulteration. When in the sample which he had examined he found white hellebore, he knew at once that it was not English root, for the veratrum plant was not grown to any extent in this country. Then there was the continental veratrum; and up to a few years since these two kinds were the only varieties in the market, the English fetching the higher price. A few years ago the cultivation of valerian was commenced in America, and it had been so successful that at the present day American valerian root fetched a higher price than any other.

A paper was then read on—

THE COLOURING MATTER OF PETALS OF ROSA GALLICA.

BY H. SENIER.

The paper is printed at p. 650, and gave rise to the following discussion:—

Professor ATTFIELD said that he trusted that Mr. Senier would carry on this investigation farther than he had already done. When he (Professor Attfield) saw the ammonio-potassium salt in the form of beautiful octahedra, he saw a means of obtaining results still more important than those already produced. If Mr. Senier would obtain some ounces instead of a few grains of the salt, he would have an opportunity of elucidating in the most important manner the composition and constitution of such colouring matter as that of the *Rosa gallicâ*.

Mr. KINGZETT said that it was rather unfortunate that the lead salt had been chosen for analysis, for it was very difficult ever to get a combination of lead which was not of a basic character. He thought that an analysis of potassium salt would have been much more instructive. There were very few instances known where a colouring matter of this kind had the power to combine with sodium, while all salts of lead had a great power of combining with a number of extractives; and, so far as he could see from the paper, no means had been taken to remove extractive other matters from the colouring substance.

Mr. H. SENIER said that the crystalline ammonio-potash salt, if decomposed by sulphuric acid, yielded the colouring matter in the red form, showing that there really was a combination of the colouring matter.

The next paper read was a—

NOTE ON THE ACTION OF DILUTE NITRIC ACID ON BRUCIA.

BY W. A. SHENSTONE, F.C.S.

This paper is printed at p. 652, and gave rise to the following discussion:—

The PRESIDENT said that this was a matter of very great interest. Mr. Shenstone had shown how brucia could be really purified if necessary, and how very difficult it was to purify it to its utmost limit. The question of the presence of strychnia in brucia was one of great importance. The activity of brucia had been considered to be one-twenty-fourth that of strychnia, but perhaps even that estimate was due to the impurity of the brucia. They had good reason to suppose that brucia, in its action on the human system, was totally different to strychnia. This paper, in his opinion, had settled the question as to whether brucia was convertible into strychnia by any oxidizing agent.

Mr. HOLMES said that he observed that Mr. Shenstone expressed some curiosity as to the source of the alkaloid experimented upon by Mr. Cownley. He (Mr. Holmes) would be glad to know whether Mr. Shenstone's brucia was obtained from the bark of the nux vomica or from the seed. He had noticed that in Pereira's 'Materia Medica,' it was stated that the bark contained brucia, the statement being so worded as to imply that it did not contain strychnia. In the 'Pharmacographia,' it was stated that the wood of the nux vomica contained strychnia, but no mention was made of the bark containing strychnia. He should like to be informed whether the bark really contained strychnine or not.

The PRESIDENT said that it was difficult to answer the question. He thought that he might say that the brucia of commerce was a by-product from the manufacture of strychnia. The brucia thus obtained was purified as highly as possible, or rather as highly as convenient, by the manufacturers. But as to the question of whether strychnia was contained in the bark of the nux vomica, he was not able to throw any light upon it.

Mr. COWNLEY said that he had made a few experiments some time ago, in order to test the statement of Sonnenschein, but was not able to confirm his conclusions. He should have been glad, for scientific reasons, if Mr. Shenstone could have established a contrary result, although personally he was happy that Mr. Shenstone had confirmed his own experiments. Whether strychnine could be separated from brucia in the way mentioned, was a point upon which the President was a greater authority than himself; but he should rather doubt the value of separating strychnia by precipitation. He should be inclined to separate these alkaloids by the relative solubility of their nitrates. As to the other point, whether brucia was capable of being converted into strychnia by these means, he should rejoice to be able to transform these and analogous alkaloids so simply.

Professor BENTLEY asked if any experiments had been made upon strychnos bark. It was always considered that if the nux vomica bark contained strychnia it was in minute proportions only. The essential activity of the bark was generally regarded as due to brucia; and that was one of the facts which had been brought forward to show that brucia as well as strychnia must have a powerful physiological action. The substitution of nux vomica bark for augustura bark undoubtedly occurred years ago. It was, therefore, particularly interesting to know whether nux vomica bark contained any appreciable amount of strychnia, or whether its poisonous action was not entirely due to brucia. In the course of a conversation some years ago with the late Mr. Morson, that gentleman informed him that the principal alkaloid in nux vomica bark was undoubtedly brucia, but he (Professor Bentley) could not call to mind whether Mr. Morson stated that the bark contained any strychnia, or whether its poisonous action was not entirely due to brucia.

Mr. HOLMES said that he had that afternoon made an experiment with the bark of the nux vomica by applying the test for strychnia. He first tried nux vomica seed and got a faint purple reaction He then tried the bark and also found a slight reaction, but still less than in the seed. He inferred from the result of this rough test that the bark did contain strychnia as well as brucia.

Mr. MARTINDALE thought that it was of more importance that they should have pure strychnia than pure brucia. With regard to the nitrate of strychnia the purity of that was of greater importance than of other salts of strychnia, as on account of its greater solubility it was useful for making hypodermic injections. He thought that in commerce the nitrate of strychnia was generally met with in a pure state; but, as nitric acid was liable to decompose it, its manufacture required great care.

Professor ATTFIELD said that he should like to give prominence to the fact that strychnia was powerfully attacked by even dilute nitric acid; and he did so because of the importance of the fact in forensic analysis.

Mr. COWNLEY said that he did not wish to detract from what Mr. Shenstone had done, but in his (Mr. Cownley's) paper they would find he had stated that the effect of the action of even dilute nitric acid on brucia or strychnia was possibly to convert it into a nitro base; or, at any rate, so to alter the character of the alkaloid that fixed alkalies failed to precipitate it; therefore the point was settled then, and Mr. Shenstone's experiments were in accordance with that result.

Professor ATTFIELD said that that important point had long ago been established, but had now been confirmed by the experiments of Mr. Cownley as well of those of Mr. Shenstone. Hence the importance of observing that the sulphuric acid employed in toxicological investigations in cases of suspected poisoning by strychnia should be absolutely free from nitric compounds.

The next paper read was on—

THE PHARMACOPŒIA TEST FOR THE PURITY OF QUININE SULPHATE.

BY B. H. PAUL, PH.D.

The paper is printed on p. 653, and gave rise to the following discussion:—

Professor ATTFIELD wished to ask Dr. Paul how he obtained his pure sulphate of quinine for his experiments. He presumed that he did so by the fractional crystallization method.

Dr. PAUL said that was the plan which he had adopted. He might mention that it was an exceedingly tedious plan, and though it was too late to go into details he might state that about five recrystallizations were requisite in order to reduce the quinine to such a state that the ether test gave no indication of cinchonidine.

Professor REDWOOD said that he must admit that the statement of Dr. Paul had taken him, to a great extent, by surprise. He was not aware and was very much surprised to find that quinine was capable of exerting so remarkable an influence upon the solubility of quinidine or cinchonidine by its simple presence, as appeared to be the case. There was no doubt that the test given in the Pharmacopœia was founded upon a knowledge of the relative solubility of the two alkaloids in their separate state, and that it was supposed that test would be sufficient to indicate the presence of comparatively small quantities of the alkaloid quinidine, as it had been originally called, with the quinine. The test certainly might, without altering its nature, have been made much more strict than it really was, as Dr. Paul had stated; but when it was considered that, in bark, quinidine, or cinchonidine, was constantly present with quinine; that the difficulty of completely separating them was very great, and that this result had not hitherto practically been attained; and when it was considered that chemical manufactures were in a progressive state, and that at the period when the Pharmacopœia was framed, manufacturers were not in the habit of getting their sulphate of quinine in so great a state of purity as was the case at the present time, they might be able, probably, to make due allowances for the fact that the test at the present time was not found to be all that they might wish it to be. There were many cases which had a direct bearing upon this, with which they had been acquainted for many years, as, for instance, the influence which one kind of oil had by its presence on another oil in promoting its solubility, or one kind of resin in promoting the solubility of another kind of resin, and it would appear that one of these alkaloids was capable of greatly increasing the solubility of the other alkaloid. They were indebted to Dr. Paul for having brought the subject forward, and especially for having suggested a process which promised very good results and would admit of being adopted when a more rigorous and severe test for the purity of quinine was called for.

Dr. PAUL said that he had not lost sight of the fact that this was an age of progress, and that, consequently, greater expectations were entertained with respect to what could be done by manufacturers and druggists than formerly. He would not attempt to suggest that there should be an absolute separation of cinchonidine from quinine in its manufacture for pharmaceutical purposes. He believed that would not only be practically impossible, but not desirable, since it would enhance the price enormously. At the present time, when there were so many extravagant notions about adulteration which were apt to cause inconvenience, he thought it desirable that some means should be taken to draw a distinction between the presence of a large amount and a small amount of impurity. There could be no doubt that between the two limits which he had mentioned there was a margin of very considerable importance in a pecuniary sense.

The meeting was then adjourned till the 7th of March.

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, Feb. 1, 1877, Professor Abel, F.R.S., President in the chair. After the minutes of the previous meeting had been read and confirmed, the following names were read for the first time:—Messrs. E. Hunter, F. C. C. Hewett, W. Terrill, A. Kininmont, J. Borland, W. H. Griffiths, and G. A. C. Pearce. Messrs. Arthur Gaved Phillips, and Ferdinand Kopfer, were duly elected Fellows after their names had been read the third time.

The President then gave notice that it was intended that the Fellows should dine together on the 20th March, and that they would shortly receive invitations. After the anniversary meeting, a special general meeting would be held to consider the regulations for admission to the Associateship of the Society, and also an alteration in the form of obligation which the Fellows sign on entering.

The first paper was by Dr. H. E. Armstrong, "On Kekulé's and Ladenburg's Benzene Symbols." The speaker, after pointing out that although Kekulé's symbol had been used almost exclusively up to the present time, Ladenburg's "prism" formula merited more consideration than it had hitherto received, said that these two symbols were in accord in representing benzene as a symmetrical compound, *i. e.*, in which the six hydrogen atoms were of equal value. This consideration was supported not only by the fact that no isomeric mono-derivatives of benzene had ever been obtained, but also by direct experimental evidence; for whichever hydrogen atom in benzene is displaced by the group OH, we always obtain the same phenol, as shown in the decomposition of the different oxybenzoic acids and similar reactions. With regard to the di-derivatives of benzene, there is no ground for supposing that more than three isomeric forms can exist; and in this respect also the two symbols are identical with regard to the number of such isomerides which they indicate. It has been urged that one of the chief reasons for the adoption of Kekulé's symbol is that the formation of additive compounds is readily explained on the supposition that when a molecule of a halogen unites with benzene, two adjacent carbon atoms united by a double affinity, each unite with an atom of halogen, and thus remain united to one another only by a single affinity. Ladenburg's prism formula, however, lends itself to a similar explanation with this difference, that it is the opposite carbon atoms in the ring, previously united by a single affinity, which unite each with a single atom of halogen, and at the same time cease to be directly united. After some observations on the difficulty of explaining the nature of the quinones, and on the influence a group exercises on others occupying the ortho- or para-position relatively to it, which could not be satisfactorily accounted for by the use of Kekulé's symbol, whilst Ladenburg's prism formula offered a possible explanation, the speaker expressed his opinion that the term para, as applied to the di-derivatives of benzene should be limited to those which were capable of yielding but a single tri-derivative, whilst those which gave rise to two and to three isomeric tri-derivatives, should be called ortho- and meta- derivatives respectively. This nomenclature, being founded on experiment, was independent of any theoretical considerations as to the so-called "position" of the substituted groups. At present, although all known facts are in accordance with the supposition that the six carbon atoms in benzene and its derivatives are united in a closed chain, we do not in the least know in what manner the atoms are united; for this reason the simple hexagon now almost universally employed to represent benzene, was preferable to the graphic formula consisting of 6 Cs, united in a hexagon by single and double lines alternately.

The President said they were all much indebted to Dr. Armstrong for the lucid manner in which he had discussed the relative value of the two graphic representations of benzene employed by Kekulé and by Ladenburg.

Dr. Odling said that it was the custom of the Society not to publish communications of a purely theoretical character, but he hoped that in this instance the publication committee might be induced to depart from the rule, so that they might have the benefit of perusing Dr. Armstrong's useful *résumé* in the Society's Journal. He quite agreed with the speaker that the evidence was overwhelming as to the existence of but a single mono-derivative of benzene of each kind; also in rejecting that form of expression for quinones which represented them as containing oxygen united with oxygen; it was in the highest degree improbable that this could be the case, considering how totally different they were from those bodies which like the peroxides were supposed to contain oxygen united with oxygen. With regard to the employment of the symbols 1 : 2, 1 : 3, etc., he thought them preferable to the terms ortho, meta, and para; as these were employed in very different senses: Körner, for instance, who might be regarded as the most prominent representative of aromatic chemistry, used them in a very different sense from that in which they were ordinarily regarded. Moreover, there were numerous benzene compounds which at one time had been regarded as ortho, but were now considered para or meta, and the reverse might be said of bodies formerly regarded as para or meta. For his own part he was in the habit of associating the various di-derivatives with the typical compounds resorcin, pyrocatechin and hydroquinone; for instance, those which could be converted into or were related to resorcin he distinguishedby the prefix reso- and so on.

Dr. Wright thought they ought all to be thankful to Dr. Armstrong for the trouble he had taken in collating facts relative to these two symbols. There was an objection to the use of the terms meta and ortho in connection with the benzene derivative inasmuch as they had long ago been applied to distinguish two of the phosphoric acids, the meta being obtained from the ortho acid by the abstraction of water; but nothing of the kind occurred in the case of the benzene compounds. He quite agreed with the speaker that these symbols should not be taken to represent any relative position of the atoms in benzene.

Dr. Odling said he might perhaps be permitted to remark that the term meta was first used by Graham to indicate that metaphosphoric acid still contained water, phosphoric anhydride being, at that time, regarded as the true acid; and he had advocated the view that those acids which had the full amount of base or basic water should receive the prefix ortho.

Mr. Kingzett made some observations on the benzene ring: he said that although for many purposes it was useful to regard the six carbon atoms in benzene to be united so as to form a closed chain, yet it could scarcely be said that the experimental proofs were absolute. On the other hand, he prefered to use line formulæ to the so-called ring formulæ, for while starting with certain bodies and operating upon them by definite means, we could predict in some measure the nature of the products, we still know little more than, that in such bodies as benzene, so many carbon are united with so many hydrogen atoms. Although with the doubtful exception mentioned by Dr. Odling, no isomeric monoderivatives of benzene had been obtained, yet it was not equally easy to substitute all the hydrogens in benzene as certain particular ones. Moreover, it must be remembered that whereas certain groups might replace hydrogen in benzene without distruction of the general structure, the products were often of a nature profoundly different to the original benzene, and even to comparable bodies in which the substituted groups was of a different kind. In connection with this subject, phenose or hexatomic benzene alcohol $C_6H_6(OH)_6$ presented some interesting characters. It was discovered by Carius, and might be regarded as benzene to which six hydroxyles had been attached; in fact, it was directly comparable to hexabrombenzene $C_6H_6Br_6$. Phenose appeared to be a true sugar, and undoubtedly differed from other sugars only in its constitution. The speaker had found that in certain reactions acetic acid could be substituted for sugar, and it was worthy of observation that if the formula of acetic acid be tripled, it is the same as that for sugar taken empirically. One conceivable formula for certain sugars was—

CH_2OH, CHOH, COH, COH, CHOH, CH_2OH.

and how far this represented the truth he and Dr. Hake had proposed to determine by ascertaining the extent to which these hydroxyles were removable. The speaker concluded by stating that in his opinion structure formulæ were to be accepted to a large extent as true only of bodies which were known to behave in particular ways in particular reactions. That is to say, the structure was rather a surmise from the reaction, and as the nature of the reaction varied with circumstances, so also the structural formulæ to be inferred might vary. In fact, it was absolutely impossible to write down a formula for a single substance and say that was its structural formula, harmonizing with all its known reactions; for teaching purposes, however, Kekule's system was useful.

Dr. Armstrong in reply to a question put by Dr. Odling, as to the difference in solubility in alcohol between ordinary potassic benzoate and that recently prepared by the action of alcoholic potash on benzoic aldehyde, first observed by Gregory, said that he did not know of any explanation of the fact. As regarded the constitution of phenose, it was not by any means satisfactorily established that it had the formula assigned to it by Carius.

Mr. Kingzett replied to Dr. Armstrong that Rosenthiel had investigated the nature of phenose, since the time of Carius's researches, and had somewhat confirmed the conclusions of the latter. For the speaker's argument, however, hexabrombenzene served all the purposes, of course, of phenose; and it was worthy of remark, that in the text-book of Dr. Armstrong on organic chemistry phenose was classed without apparent reservation among the sugars, and no doubt was there expressed about its formula.

The next paper was by Mr. W. H. Perkin, "On the Formation of Coumaric and of Cinnamic and of Other Analogous Acids from the Aromatic Aldehydes." The author, after adverting to a preliminary notice on the subject, read before the Society in 1875, gave a brief account of some of the numerous substances he had obtained. He found that on boiling benzoic aldehyde with acetic anhydride and sodium acetate, an action took place with formation of an acid, which after purification was found to be identical with cinnamic acid. When sodium propionate and propionic anhydride, were substituted for the acetate, phenyl-crotonic acid, $C_6H_5.C_3H_4.COOH$ was obtained. It crystallizes in fine colourless needles which melt at 82°-84°C. Phenyl-angelic acid, $C_6H_5.C_4H_6.COOH$, was prepared in a similar manner by the employment of butyric anhydride. It crystallizes in needles which melt at 101°C. With succinic anhydride, an acid was obtained having the same composition as phenyl-crotonic acid, but very different in properties; it has been named isophenylcrotonic acid. Experiments were made in a similar manner with other aldehydes, namely, cuminic, cinnamic, anisic and methyl-salicylic, which gave rise to sixteen other acids. It was found that the calcium salt of cumenylacrylic acid, obtained from acetic anhydride and cuminic aldehyde, when heated to 90°-100°C. absorbed an atom of oxygen, and was converted into the calcium salt of a new acid, which is now under investigation. Cumenyl-acrylic acid also, when treated with sodium amalgam in the presence of water, takes up a molecule of hydrogen, giving rise to a crystalline *hydro-cumenyl-acrylic acid*, which melts at 70°C. Cumenyl-acrylic acid when gently boiled undergoes decomposition, carbonic anhydride is eliminated, and a hydrocarbon $C_6H_4(C_3H_7)(C_2H_3)$, *isopropylvinylbenzene* is formed. It is an oil boiling at 195°-200°, and possessing a fragrant aromatic odour. The *methyl-paroxyphenyl-crotonic acid*, obtained from anisic aldehyde and propionic anhydride, under similar circumstances gave rise to anethol $C_6H_4(OCH_3)(C_3H_5)$, whilst the corresponding acrylic and angelic acids gave rise to the homologous compounds $C_6H_4(OCH_3)(C_2H_3)$ and $C_6H_4(OCH_3)(C_4H_7)$. By heating methylsalicylic aldehyde with acetic, propionic, and butyric anhydrides respectively, in presence of the corresponding sodium compounds, three acids were obtained, namely, *methyl-orthoxyphenacrylic acid* or *methyl-coumaric acid*, $C_6H_4(OCH_3)C_2H_2.COOH$ *methyl-orthoxyphenyl-crotonic acid* $C_6H_4(OCH_3)C_3H_4.COOH$, and *methyl-orthoxyphenyl-angelic acid* $C_6H_4(OCH_3)C_4H_6.COOH$. The methyl salt of an acid having the same composition as the first of these acids (methyl-coumaric acid) is obtained when the sodium derivative of coumarin, prepared by boiling it in alcoholic solution with sodium hydrate, is heated at 100° C. with methyl iodide. On saponifying the ether, it yields an acid isomeric with methyl-coumaric acid, and melting at 88°-89°. The author calls it a *methyl-orthoxyphenyl-acrylic acid*. This methyl salt when heated at 150° C undergoes isomeric change, and now, when saponified, yields an acid fusing at 182°-183°, identical in all respects with that obtained from methylsalicylic aldehyde and acetic anhydride. The fusible acid itself, also, when heated to its boiling point passes into the isomeric modification of higher fusing point. The author described numerous salts of the various acids also the iso-chlorides and the amides, and concluded with some theoretical considerations as to the manner in which the acids are formed in this reaction, and their probable constitution.

Communications, Letters, etc., have been received from Messrs. Clifford, Piper, Green, Warren, Brown, Chorley, Starke, Fairlie, Ellinor, Slipper, Reynolds, Smith, Long, Baker, Jevons, Rheum, Kino, Dispenser, Inquirer, Molar, Gelosa, D., Z.L.

INCOMPATIBILITY AS APPLIED TO MEDICINE.*

BY FRANCIS W. E. MOINET, M.D., F.R.C.P.E.,

Lecturer on Materia Medica and Therapeutics at the Edinburgh School of Medicine.

My reasons for choosing incompatibility as applied to medicine for the subject of a few remarks are twofold, viz:—first that there appears to me to be very frequently a good deal of confusion, or diversity of opinion, both on the part of prescriber and dispenser, as to what the term really means and to what it ought to be applied; and secondly, to notice briefly the causes of this confusion, and then to try if some conclusion can be arrived at to guide to a correct understanding of the term.

No doubt all are aware what the word means in common parlance, viz., opposed to, or incapable of combined or harmonious action, and the disagreeable results that sometimes occur, when, for instance, the tempers of two individuals possess this quality. Well, in chemistry the meaning is somewhat similar when the term is applied to two or more substances which are not capable of being united in solution without liability to decomposition or other chemical change, very often with the result that a precipitate is thrown down.

While then this is what is generally meant by incompatibility in every-day language and as used in chemistry, I wish to have it remembered that it is very often wrong when applied to medicine, because with the progress of chemistry and the advance of our knowledge of physiology and the action of medicines, if the word is to be retained, and I see no reason why it should not, its meaning must be extended and better defined, otherwise endless mistakes will be made and greater confusion arise in the future.

Another cause, to my mind, of this confusion, especially among students is, and it is one for which to a certain extent I must blame myself, that lecturers on materia medica seldom discuss the subject, on account of want of time,—at least I speak for myself, —and also that works on materia medica either pass it over entirely or treat it very cursorily and imperfectly, simply giving a list of the more important chemical incompatibles at the end of the notice of each drug, but not a word as to the *rationale* of their incompatibility. Besides it will be found that as a rule the majority of the incompatibles mentioned are never by any chance likely to be prescribed together on account of any fitness they have for each other in their therapeutical relation to meet the requirements of the physician; so that they are only apt to confuse the beginner, and even if he remembers them it is a needless waste of trouble. Students are thus left to shift for themselves as best they can, to trust to their memories, or to get some knowledge of the subject in their practical work; and although no doubt this knowledge is better than none, still it is meagre and unsatisfactory at the best, unless they can give the "reason why" of their opinions.

Some, on the other hand, understand the term in a purely chemical sense, which was the old method, viz., to condemn as incompatible all substances which form a compound insoluble in water. But this, as we shall see immediately, is too limited a view to take of the subject. Still I do not wonder that this remained the prevailing idea so long, and even yet continues to be so with some Because if the dispenser's knowledge is to be confined simply to the chemistry of materia medica, the preservation, purity, and preparation of drugs, as it long was, he naturally looks no further than presenting as nice a looking mixture as possible, taking no heed what are the probable objects for which it is to be given, or to fulfil what indication it has been prescribed, so long as it does not infringe the laws of his chemical knowledge. But now that more is expected from the dispenser of drugs, and rightly so I think, and as your own body have for some time believed and acted upon that belief, a knowledge of the action of medicine is required. Hence he must look beyond the bottle and consider if the mixture is incompatible with the known action of the ingredients. It is not necessary that you should know all the uses of a drug, or the diseases for which it may be ordered by the physician, but simply its physiological action and its effects in medicinal doses. And if the mixture is not incompatible with these, it is not incompatible at all in a therapeutical sense, which is the only incompatibility that we have to consider.

Thus it will be seen the meaning of the term is already extended. The chemical definition is no longer sufficient, because although chemical changes take place, it does not by any means follow that the efficacy of the prescription is impaired. The reason why chemical does not necessarily imply therapeutical incompatibility, is that we must take into account the solvent power of the gastric and other intestinal juices acting under the influence of vital force, which cannot be judged by the ordinary chemical laws as manifested in the laboratory of the chemist, as living beings can dissolve, appropriate, and circulate in their fluids substances which to ordinary agencies are most intractable and insoluble. So that, while in chemistry the term has a definite meaning about which there cannot reasonably be a difference of opinion, when applied to medicine the case is different, as it is not then simply a question of chemical ethics; it is not only the condition as to the solubility or insolubility of a medicine that has to be considered, although undoubtedly these are sometimes most important points, but the effect on its activity, that is its action on the animal economy. Hence the reason why the chemical definition is too limited. It may be, and is correct in some instances, that the condition interferes with the action of the prescription, but not in all, and even when it does it is, as it were, only by chance, as the definition does not imply it, nor does it logically follow. Neither can we expect it, as the definition was made without any reference to its application to medicinal compounds as affecting their activity. This is the reason why at the present day in prescription writing chemical incompatibility is so frequently disregarded and must be, and if we wish for examples we have them in plenty in the Pharmacopœia itself. Take for example Pil. Plumbi c. Opio, Lotio Hyd. Nigra and Lotio Hyd. Flava, Mist Ferri Aromat. Vinum Ferri, etc.; also many new compounds or salts are made by the action of incompatibles on each other, as by neutralizing acids with alkalies, and by decomposing salts by strong acids. These are a few instances of chemical incompatibility, and yet they

* Read before the North British Branch of the Pharmaceutical Society, January 31, 1877.

are advisedly made use of together, as thereby the action of the preparation is increased, or new compounds are formed equally or more active than the original substances. So that some prescriptions and preparations are framed designedly to take advantage of chemical incompatibility for the advantage of the patients. Thus a very common prescription is a lotion containing laudanum and subacetate of lead. Then again alkaloids and vegetable infusions containing tannin give precipitates, and for this reason such infusions are sometimes recommended as antidotes in poisoning with the alkaloids; but we know that the tannates are soluble in the gastric juices, and that in this condition their solubility is only a matter of time, their action being delayed only for a very brief space which is taken advantage of to get rid of the poison from the stomach. The tannates of iron are also soluble, but prescribing them in this form can easily be avoided without loss of activity. Then also albuminate of corrosive sublimate, which presents corrosive sublimate in the most insoluble form possible, and for this reason is the best antidote we have for it in case of poisoning with it, has been highly recommended for internal administration as being the preparation most easily borne by the stomach, and its action being mild and certain. So that it will be readily understood that a chemically incompatible mixture may be medicinally active because, although insoluble in the bottle, it may be dissolved in the stomach by the gastric juices, and that if new compounds are formed they may be equally or more active than the orginal substances. Hence before condemning a mixture whose components are chemically incompatible, we must ask ourselves the following questions:—

1. Whether the new product although insoluble in the phial may not be soluble in the gastric juices?

2. Whether as a result of a change, the new compound or compounds be equally active as a medicine?

3. If, in a case of decomposition, the products of exchange are equal in energy to the original substances?

As a general rule, however, we must carefully avoid the combination of substances which may produce unknown or ill-defined compounds or compounds different from those intended, or whose action is different; hence a knowledge of their composition and action must in every case direct us.

It will be seen then that the chemical definition of the term is not sufficiently comprehensive for our purpose, for the reasons I have mentioned, which permit so many exceptions.

But from what I have said it must be not for a moment inferred that I wish to underrate the importance of chemical incompatibility, only that it should be known definitely to what alone it ought to be applied. In point of fact that we should neither underrate, or overrate, but justly appreciate its significance, and a moderate amount of chemical knowledge is quite sufficient to enable us to do so, and prevent us falling into either extreme of avoiding all chemical incompatibles, or disregarding all; because in the former case we should greatly limit our resources in the treatment of disease, while in the latter we might be giving useless or even dangerous compounds. For instance, if we mix acids and alkalies in certain proportions when we wish the action of an acid or alkali, or give the caustic alkalies (Garrod) with preparations of belladonna, hyoscyamus, or stramonium, the effect is *nil*. On the other hand, we may have new compounds formed which we do not want, as calomel with iodide of potassium or hydrochloric acid would be converted, respectively, into the red iodide of mercury and corrosive sublimate; or by adding metallic oxide and acids, which form salts whose properties are often different from either the acid or oxide.

And while the older practitioners attached too much importance to this form of incompatibility, the new school is just a little inclined to rush into the other extreme. This is no doubt due to a kind of reaction which has of late years taken place, and like most reactions is a little apt to be carried too far, namely, to disregard chemical incompatibility almost entirely. This, I need hardly repeat is an error in the other direction, that ought to be most carefully avoided, as it is one fraught with danger to the patient. Thus, for instance, the soluble iodides are incompatible with alkaloids and substances containing them, because the alkaloids are precipitated, and the patient, instead of getting the dose which was intended, may get it all at once, and so serious consequences ensue, *e.g.*, the case related by Wood, in which death occurred from a prescription containing iodide of potassium and strychnine, all the strychnine being taken at the last dose.

This was due to chemical incompatibility, which in this case practically infers therapeutical incompatibility, as the dose was transformed from a medicinal to a poisonous one, and its action for a physician's purpose defeated, not to mention the effect on the patient and the consequence to the rash prescriber. Again in other cases, although the effects may not be so dangerous or startling, the patient may be taking some compound different from what was intended, or an inert preparation, and so if it does no bodily injury, at least it is wasting time and money which are important aids to recovery, and at the same time exposing the ignorance of the physician.

I need not take up your time with further examples of this form of incompatibility, as many will naturally occur to you, and the only thing to prevent us going to either extreme is a knowledge of the proper meaning of the term, based upon a knowledge of those branches of study viz., chemistry, materia medica, and therapeutics, which alone form the proper groundwork for the rational prescribing or dispensing of medicines. When, then, it gradually dawned upon the profession that the chemical definition of incompatibility was too meagre and far from satisfactory, an advance was made in the right direction, and a more comprehensive definition was attempted, termed medicinal incompatibility, viz., not suitable to be prescribed together without interfering with their chemical composition or medicinal activity. This definition is also, however, too absolute for our purpose, because, as we have seen, chemical does not necessarily imply therapeutical incompatibility; and secondly, that one substance may interfere with the medicinal activity of another, and so assist the action of the prescription instead of retarding it. This being one of the reasons for the combination of remedies, to lessen or to increase their action or to correct some disagreeable or hurtful property, or even to change their action entirely by the formation of new compounds. And while this certainly interferes with their activity, at least with one kind of activity, it does not necessarily defeat the purpose for which it was prescribed, provided always such results were calculated upon beforehand.

The next question is then, Can the action of remedies be interfered with when in combination in any other way than by what is due to opposing chemical properties? If not, chemical incompatibility when it defeats the purpose of a prescription would be the only form.

This, however, is not the case. So that we must, to understand the terms properly, see what a definition ought to embrace if it is a complete one and logically correct.

To do this we must look beyond the prescription and see for what purposes it has been written,—that is, its action. The neglecting to do this is one of the reasons that we hear the term incompatible so much more frequently employed by the younger members of our profession; but as with increase of knowledge and experience they begin to ask themselves the reason why of many of their former opinions as to incompatible mixtures, they find that they will not bear scrutiny, because they now bring to bear upon them not only their chemical knowledge, but also their knowledge of the action of remedies, and have two questions to answer instead of one, viz., If it is an instance of chemical incompatibility, is it also one of medicinal, or as it is sometimes called, physiological or therapeutical incompatibility? If not it cannot be fairly condemned, although in some cases without any sacrifice of its utility, the chemical incompatibility might easily have been avoided.

But although the ingredients of a mixture may not be chemically incompatible, yet their physical properties may be such as to interfere or defeat the intended operation, and that without any chemical change taking place. What, in fact, Dr. Paris calls an error in the mechanism of the prescription, and which has generally been regarded as more inconvenient than dangerous, more fatal to the credit of the practitioner than to the ease of the patient. But they are not always harmless.

Examples of this condition are not uncommon. Thus pills, in consequence of ill-assorted ingredients, may be so hard as to be perfectly useless, or substances may be ordered in pills, which will not retain their form, or mixtures may be given that will not pour out of the bottle, or substances may be ordered in powder which liquefy when triturated together, or liquids ordered of such different specific gravities that they separate into distinct layers on standing. Such then are a few examples of the condition, and which is certainly not free from danger. So that not only the chemical but also the physical properties of certain substances may be a bar to their action, either by not presenting them to the system in a condition favourable to their action, or in a condition not suitable for administration by preventing proper mixing of the ingredients and so altering the dose either to a smaller or larger one than is wanted; in the latter case with the chance of the usual effects of an over-dose. For these reasons a prescription or preparation may be an example of a form of incompatibility which may be termed pharmaceutical in contradistinction to chemical, and be due to the physical properties of the substances used.

But even supposing a prescription complies with the rules of chemical and pharmaceutical compatibility, there is another question which occasionally must be considered owing to the advance of our knowledge of the action of medicines, viz., their antagonistic action, which is so well marked, for instance, in the case of the action of atropine, the active principle of belladonna, and physostigmine, the active principle of calabar bean. It was first pointed out by Dr. Fraser that under certain conditions as to dose and time of administration the one would ward off or prevent the fatal action of the other, and for this reason their actions on the animal economy are said to be antagonistic or opposite, and so the full activity of either is prevented. This will be understood better if we look at the antagonism of atropine and physostigmine as seen in their action on the pupil.

Thus, the iris, which is a thin coloured membrane hanging behind the transparent cornea, and which gives colour to the eye, is perforated at its centre by an aperture, which aperture is circular, and is termed the pupil. The muscular fibre which composes the iris is arranged in two groups, one arranged in a ring round the pupil, which is the muscle that causes contraction of the pupil and diminishes its size; the other muscle has its fibres arranged at right angles to the former, and is termed the dilator muscle of the pupil. Now suppose we apply a little belladonna to the eye, what is the result? Dilatation of the pupil very speedily occurs, due to its stimulating the nerve fibres which supply the dilator muscle and paralysing the nerve fibres which supply the circular fibre of the iris or contractor muscle. If, on the other hand, we apply a little physostigmine to the eye exactly the opposite effect is produced, namely, contraction or diminution in the size of the pupil, due probably to its paralysing the nerve fibres which supply the dilator muscle and stimulating those which supply the contractor muscle. In this way their actions on the pupil are exactly opposite or antagonistic.

And what is seen to take place in regard to their actions on the pupil takes place to a certain extent in regard to their action on other parts of the nervous system.

Thus also with the action of aconite and digitalis on the heart, the one depresses and weakens its action, the other stimulates and strengthens its action, so that if given in certain doses and within certain limits of time, the one will restrain the action of the other, and the heart will remain unaffected. This antagonistic action is not due, remember, to any chemical change, but to their actions on certain parts of the nervous system being of an opposite nature, and so neutralizing each other; that is, what are termed the dynamical or vital properties of remedies, as distinct from their chemical or physical, are incompatible.

This then is an incompatibility of a third kind which although not so frequently met with as the others, must receive its due share of attention if we are to look at the subject in its completeness.

This antagonistic action, however, may be taken advantage of and be of service to the physician; as, for instance, in an overdose of aconite, which endangers life by its depressing action on the heart, by the timely use of digitalis a fatal result may be warded off.

A case was related in the *British Medical Journal*, December, 1872, by Dr. Dobie, in which recovery took place after the ingestion of one ounce of

Fleming's tincture of aconite due to hypodermic injection of digitalis.

Thus also chloral hydrate acts in cases of poisoning from strychnine. So that even this antagonistic action is not in all cases a barrier to the employment of such remedies together, as these combinations may be of great service by fulfilling indications in the treatment of disease, and examples are not infrequently met with in nature. This is one reason why in certain cases active principles do not always represent entirely the action of the crude drug. Thus rhubarb contains a purgative and an astringent principle, which principles are undoubtedly to a certain extent antagonistic in their action. But in this instance the astringent matter is only present in such a small proportion as to modify, not defeat, the action of the purgative principle or principles, and this combination renders rhubarb such a valuable remedy in certain cases, as its action is not apt to be severe. Take also a very common and useful prescription, laudanum and castor oil, where the same principle is made use of for the treatment of certain intestinal derangements.

So that you see that all rules apparently must have exceptions, and such is certainly the case with those regarding incompatibility. But looking at the subject as we have done, thus briefly, it will be understood that incompatibility may be of three kinds when applied to medicines, viz:—

1. Pharmaceutical.
2. Chemical.
3. Physiological, therapeutical or medicinal.

The first by reason of their physical properties; the second by reason of their chemical properties, and the third by reason of their dynamical or vital properties interfering with the action by which a prescription or preparation might be curative or salutary, its activity being lessened, increased, perverted or entirely annulled.

Or we may put it another way, namely, that the action of a prescription may be interfered with by pharmaceutical, chemical or physiological incompatibility, all of which propositions are included in the following definition:—

Not suitable to be prescribed together on account of their activity being interfered with by their *physical*, chemical or dynamical properties.

If then I have been successful in making the subject of incompatibility at all clearer, I hope at the same time that I have made it equally clear, that the only way either for prescriber or dispenser to avoid falling into the error of prescribing or dispensing incompatible mixtures is a knowledge of chemistry, materia medica and the action of drugs, otherwise it is impossible for him to understand the subject, as it ought to be understood by those who are licensed either to prescribe or dispense. And it is a knowledge for ignorance of which we can be justly held responsible, and a knowledge that is inseparable from the art of either prescribing or making a useful preparation.

The discussion which followed the reading of this paper will be found on p. 679.

PRESENCE OF CINCHONIDINE IN THE QUININE SULPHATE OF COMMERCE.

BY B. H. PAUL, PH.D.

The accompanying table gives the details of the results I have obtained in the analysis of nine samples of the quinine sulphate prepared by various manufacturers. The samples were in all cases tested to ascertain the amount of crystallization water by drying at 212° F. in a weighing glass capable of being perfectly closed as soon as it was removed from the steam-bath. If this precaution be taken the salt remains anhydrous, but if contact with the atmosphere be permitted some water is rapidly absorbed by the anhydrous salt.

The plan adopted for separating the cinchonidine sulphate was to recrystallize by dissolving four or five grams of the salt in 80 to 150 cubic centimetres of boiling water and after cooling to filter off the liquid, which was then shaken with sufficient ether to leave a distinct layer undissolved. On the addition of ammonia solution in excess, the alkaloid separated was in most instances only partially soluble in the ether; with the samples containing least cinchonidine the whole of the alkaloid was at first dissolved by the ether, but after the lapse of a few hours the cinchonidine was deposited in the form of crystals which were collected on a filter and weighed.

The quinine sulphate separated on cooling the hot solution was again recrystallized in the same way as at first, and the mother liquor was treated as before with ether and ammonia. In this way a further quantity of alkaloid insoluble in a moderate proportion of ether was obtained, and by repeating the recrystallization of the salt a third time another smaller quantity was obtained. The mother liquor obtained by a fourth recrystallization gave no evidence of cinchonidine so far as treatment with ether was capable of indicating its presence.

The first six samples were taken from sealed ounce bottles of which only No. 3 had been previously opened. In all these instances the amount of crystallization water was not much different from that normally appertaining to the salt, viz: 14·45 per cent. The smaller amounts of water in the samples No. 7, 8, and 9 were probably due to some degree of efflorescence, since these samples had been for some time exposed to the air. So that making allowance for this circumstance the proportions of cinchonidine sulphate in the original salt would be somewhat less than those stated as the result of analysis.

Apart from the loss attending the operation, the amounts of cinchonidine sulphate indicated by these results are to be regarded as in all cases minimum amounts inasmuch as some cinchonidine still escapes separation by ether.

No. 1. Contained 15·05 per cent. water.

JAPANESE MEDICINE AND PHARMACY.*

The peculiar geographical position of Japan, together with its intimate and for many centuries exclusive intercourse with China, have been the means of transplanting many branches of knowledge and various useful arts from the latter country to the former; among these, Japanese medicine is entirely based upon Chinese authorities, and although European science, thanks to the enlightened liberality of the present Government, is gradually making progress, the bulk of the native practitioners still adhere to the old tenets.

Tradition speaks of a time when there existed a native Japanese system of medicine, but no traces have remained of it, and for more than 2000 years all medical and pharmaceutical knowledge of the Japanese has been derived from Chinese sources. The latter, contrary to what might be expected from the copiousness of literature in other branches, are exceedingly few and scant, and consist mainly of these two works:

1. The *Shookánron* ("Doctrine of the Febrile Diseases,") which was composed about 350 B.C., by Tchoochúke, the Chinese Hippocrates.

2. The *Kinki* ("Golden Chest"), which treats of all diseases excepting fevers.

But it must not be supposed that the Japanese practitioners were exempt from the natural tendency to opposition, which in more civilized countries has showered upon us a harvest of "pathists" too long to enumerate; on the contrary, in olden times already there arose a schism between the followers of the fever-theory of the Shookánron,† and the champions of the other school, which recognized both works. The former, who were specialists in our sense of the word, maintained that the treatment of all diseases, febrile or otherwise, may be learned from their authority, while the latter, being more progressive or liberal, acknowledged the authority of both, and even ascribed the authorship of the Kinki to Tchoochúke himself.

Besides these two principal works, the liberal school recommend a number of other Chinese books for the study of medicine, the importance or authority of which is considered to increase with their age. The principal ones are:

1. *Somon*, that is, "Catechism of Soko," an omniscient deity, who gives answers to questions put to him by Hoanti, the son of Hohi,‡ on human diseases. It is interspersed with philosophical, physiological, and anatomical disquisitions.

2. *Réissu* ("Holy Centre"), likewise very old, and of similar contents.

3. *Honzo*, a materia medica of more modern origin, about 200 years old; it treats of the remedies arranged according to the three kingdoms of nature, giving a description of their physical and external forms and characteristics, and an account of their therapeutic use. Besides those remedies, which are used in China exclusively, some others, not Chinese, are treated of in this work, as opium, asafœtida, gentian, sal ammoniac, etc.

4. *Ungekiron*, a treatise on pestilence, about 200 years old; of much inferior authority.

Chinese books of less age than about 200 years are looked upon as devoid of all authority, and in general no work is adopted as a standard until it has stood the test of time in China for several generations.

The introduction of European medical science into Japan, which met with but little success before the beginning of the century, may be said to have begun with the labours of Dr. von Siebold, who, with the consent of the Japanese Government, instructed a number of natives privately in natural history, and who also succeeded in introducing vaccination into Japan in 1824. His labours were continued by his successors at Desima until the Government established a regular medical schoo, at Nagasaki in 1857, which was followed by another at Ozaka in 1872; the latter, however, was afterwards incorporated with the medical department of the University at Tokio. But, although much progress has been made to disseminate European medicine among the medical practitioners of Japan, it is useless to expect much improvement until the learning generation shall have taken the place of the practising one.

It has been stated that the main source of knowledge of materia medica is the Honzo. But in reality there are three works, which supplement each other, and of which the first may be termed Honzo—κατ' ἐξοχήν.

1. *Hon-zo-ko-moku* (Chin. *Pun-tsao-kang-muh*).
2. *Hon-zo-ko-moku kei mi.*
3. *Yamoto-hon-zo.*

The first is originally a Chinese work, begun at the command of the Emperor Kea-tsing, by the celebrated Le-she-chin, and after his death completed by his son, in 1596. It is very voluminous, consisting of fifty-two portions, generally bound in forty volumes, with two or three volumes of maps. The first two parts contain an introduction and general practical rules on therapeutics: parts 3 and 4 give a general summary of remedies, part 5 describes various forms of water, part 6 those of fire, part 7 the earth, part 8 the metals and gems, parts 9 and 10 minerals in general, part 11 saline minerals and salts; parts 12 to 38 describe medicines derived from the vegetable, and parts 39 to 52 those derived from the animal kingdom. The maps contain about 1200 figures. It describes altogether 1890 remedies, and is said to be a compilation from more than 800 authors on materia medica and medicine, executed by order of the emperor, and, up to within a short time ago, the recognized official authority. The first Japanese edition appeared at Yeddo in 1714, being edited by Ina Wakasui.

The second of the above-named works, Hon-zo-ko-moku kei-mo ("The Honzokomoku's Obscurity Dispeller"), is a commentary on the first work, composed by the well-known Japanese botanist, Ono Ranzan, and published in 1804, simultaneously at Kioto and at Yeddo; again in 1847. His descriptions are remarkably accurate, and his work may be considered as a pharmacognosy of Japan. It consists of 48 parts, generally divided into 31 volumes.

The third work, the Yamoto-hon-zo was composed in 1709, by Kai-Bara, and printed in Kioto. It is a handbook of the natural history of Japan, and of purely Japanese drugs. It makes no allusion to therapeutics. It consists of sixteen parts in eight volumes, with a supplemental volume, and a volume of botanical plates, which, however, like those of the Hon-zo-ko-moku, are often very inaccurate.

The system of native medical education hitherto in vogue, and still followed in Japan, is based on a sort of apprenticeship; one class of pupils entering the house of their preceptor as "free" scholars, but paying for their education and support; another class entering the service of their preceptor, and for the sake of the instruction received or expected, doing all sorts of menial offices, as compounding medicines, bathing the sick, acting as errand boy or nursery-maid, etc. The "free" scholars may devote their whole time to study, generally pay an entry fee of ½ rio,* and offer presents every six months. All pupils must possess the necessary preliminary knowledge, which consists in being able to read and write Chinese fluently, to know Chinese history, and to be able to make prose and poetical compositions in Chinese. As all the standard medical works are written in Chinese, and only such a course of study as the above mentioned can give sufficient knowledge of this language, no student can be exempted from it. The pupil must be at least sixteen years of age when entering. He is at once given the

* From *New Remedies*, January 15, 1877.

† The translation of the Shookánron, without comment, would scarcely fill 100 octavo pages.

‡ The reputed founder of the Chinese empire.

* 1 rio = \$1.05; 1 rio = 4 bu (itzebu); 1 rio = 50 momme; 1 momme = 10 fun.

Shookánron for study, which, as before stated, is the exclusive authority of the Old School (Kohō), while the disciples of the New School (Kōsse, post mundane) have to study also the other standard works.

The practical or clinical instruction consists merely in the permission to be present during the consultations or visits of the teacher, who never gives explanations of his diagnosis, but whose manners, mode of manipulation, demeanour, and consolatory discourse, must be acquired by mute observation and unaided imitation. At the end of such a *séance*, the teacher dictates to one of the pupils, whose special duty this is, a number of receipts, with number and name of patient, into a large prescription-book, which is generally copied by all the pupils. The amanuensis also prepares every prescription, at which occasion he proceeds with a great deal of leisure, as it is considered more conducive to the reputation of the physician to have patients detained in his house for a long time, such as half a day or more. At the end of two years' instruction, the pupils are declared competent, when the "free" or paying scholars generally go to Tokio (Yeddo), or Kioto (Miako), or Nagasaki, for further study, while the "bonded" pupils have to give their services as assistants for another year to their instructors.

It would lead us too far to give here an account of their theories and speculations regarding the origin and division of diseases, or their explanation of the mode of treatment. Suffice it to say that their chief observations are made upon such symptoms as call for the employment of any of their four chief classes of remedies: diaphoretics, cathartics, emetics, and narcotics.

Most of their remedies are of vegetable origin, the most important, according to the Honzo, being the following:

Nindjin, a species of carrot, valued as a panacea, and sold at the rate of about eight dollars per ounce. It is cultivated in Japan, but, like many other remedies, must be sent first to China and then reimported, to be of value. It must be administered in very large doses, whence only the rich can afford to be "cured" by it.

Buschi, root of *Aconitum Chinense*, used in paralysis and generally all nervous diseases.

Natural pearls, whole or powdered, used in ophthalmic affections.

Bear's bile, considered nearly equal to nindjin, and very expensive.

Musk and *camphor*, important nervine remedies.

Goo, or dried bullock's brain; a favourite remedy in infantile convulsions.

Retengai, pieces of decayed human skulls, considered of value in the treatment of phthisis.

Tatsuno otoschingo ("Posthumous Son of the Dragon") are dried salamanders, being the principal remedy in infantile marasmus and diarrhœa.

Sad-juzu (*Atractylodes lancea*), and

Biaku-juzu (*Atractylodes nova*), are both much used as antifebrile remedies.

Kobusi (*Cyperus rotundus*), used as diaphoretic and antispasmodic.

Biwa (*Eriobotrya Japonica*), important prophylactic against summer complaints.

Nindoo (*Lonicera Japonica*), universal remedy against skin diseases. A decoction of it is used externally.

Botan (*Paconia moutan*) is considered abortive. It is, however, not used as such, but is forbidden to be eaten by pregnant women.

Boscho (*sodium sulphate*), used as cathartic.

Daio (rhubarb), the principal cathartic and laxative; termed "the king of all remedies;" only *daio* is believed to be powerful enough to expel all poisons from the body.

Kuatté (powdered flowers of a species of melon), used, in large doses, as emetic.

Mao, a graminea, used in decoction as diaphoretic.

Opium has been introduced in more recent times.

Much used are besides: *Hakko* (*Mentha piperita*), *Dsio* (*Melissa*), *Uikio* (*Pimpinella anisum*), *Seisin* (*Asarum Canadense*), *Intsin* (*Artemisia capillaris*), *Dokkatzu* (*Aralia edulis*), *Nikkei* (*Cinnamomum Loureiri*), etc.

The form in which remedies are exhibited is considered to be of great influence upon their effect. They are mostly compounded according to general directions contained in the Shookánron and Kinki, only modified by leaving out, substituting, or adding certain articles, for special purposes.

Decoctions are the most common form of administration; they are generally prepared by the patient or his attendants, from material furnished by the physician, and unless specially interdicted by the latter, always prepared with the addition of ginger, "which is considered to guide them to their appropriate place in the body." Other common forms of remedies are confections, prepared from honey and vegetable powders; suppositories, already recommended by the standard old authorities; powders, and pills; ointments, prepared from mutton-tallow, oil, and vegetable powders; and plasters, prepared from litharge, oil and turpentine.

Medicines are generally weighed, the more costly ones always; ordinary remedies are often measured out with little spoons. But this is always done in the physician's "dispensary." There are no apothecaries in Japan, only dealers in simple drugs, or certain standard compounds, which are sold to the people at large, or to physicians, who alone know how to compound a complicated recipe. The necessary remedies for sudden emergencies are carried by every practitioner in the *Inroo* ("stamp-keeper"), a box containing four compartments, and carried on a string fastened to the girdle over the right hip. In one of these compartments must always be contained a mixture termed *Kitzuke* ("recalling power"), consisting of storax, honey, musk, camphor, cloves, terra japonica, incense, etc. This is given in all dangerous attacks, as syncope, angina pectoris, convulsions, palpitations, etc. Another compartment contains dried bear's bile, which is also considered as highly effective in convulsions and other diseases. The other two spaces are filled according to the practitioner's own fancy.

The choice of remedies depends upon the result of the diagnosis. The latter is made chiefly from an examination of the pulse. A skilful physician is expected to correctly recognize and prognosticate the disease, without oral inquiries, merely from an examination of the pulse. The medical authorities contain a minute and detailed exposition of the variations of the pulse and its relations to various diseases, and show in this particular, as in many others, much relationship to the systems of medicine in vogue among the ancient Hindus and Greeks.

In the following we append a summary of the contents of parts 5, 6, 7 and 8 of the Japanese Pharmacopœia contained in the Honzo.*

Rain-water (especially collected during spring), lake-water, dew-water, moon-water (collected under the rays of the moon on a metallic mirror), hoar-frost water, snow-water, hail-water, ice-water (among other uses recommended, mixed with Ama-sake, for "Katzenjammer"), bambus-water, water drained through old roofs (considered poisonous, used as an antidote for mercurial poisoning, or against rabies), river-water, well-water (considered injurious, and avoided for the preparation of tea, which becomes dark coloured), well-water collected on the first day of the first month, or the second day of the second month, etc., sweet water from Mino and Omi, water containing bicarbonate of calcium (niyu ketsu), warm mineral water (no less than two hundred and forty-nine mineral springs are known to exist in Japan, some of these of considerable richness in important therapeutic constituents), sea-water brine (used in scabies), spring-water from rocks, putrid water collected about old posts,

* Cf. *Mittheil. d. Deutsch. Ges. f. Natur-u. Völkerkunde Ost-Asiens*, No. 3, Yokohoma, 1874.

water from corpses (collected by placing empty cups into the coffins, and withdrawing them after the decomposition of the cadaver (used internally in mania, and also externally), water through which snakes have passed, vinegar-water (prepared by allowing a decoction of millet and awa to undergo fermentation), condensed water (from rice-boilers), water boiled in copper kettles, grindstone-water, pigsty-water (antidote against poisons), water in which new-born infants have been washed, rain-water collected in empty bladders ("the patient must not know the *origin* thereof"—which caution we should imagine would be applicable to many other remedies in their catalogue), and various others. The succeeding part of the work contains an account of various forms of fire and agents for combustion: male fire (actual burning fire), female fire (all phenomena of phosphorescence, or luminousness without actual flame), fire produced by friction of wood (supposed to be only obtainable from *Retinispora obtusa*, or *Hinoki*, and *Meliosma rigida*, or *Yama biwa*), wood-charcoal, charcoal of various kinds of wood (much used in large lumps or logs, for the absorption of noxious vapours or effluvia in houses); moxa-fire (the leaves of *Artemisia Chinensis*, pounded and dried and placed upon affected portions of the body, where they are ignited; moxas are much in use as counter-irritants, and in rheumatic or gouty diseases); actual cautery (highly esteemed in rheumatism; it consists of round or square iron plates of about three square inches, with a central handle); lamp-fire, burnt wicks, native coal, petroleum (sekinoyu; besides the usual industrial applications, it is used for preparing a special kind of lampblack, which is said to give to the better grades of Japanese and Chinese India inks their peculiar lustre), soot. Then follow: sulphur (two, crude or sublimed), rock-crystals, amethyst, river sand, quartz, agate, chalcedony, opal, obsidian, pumice (decoction in diabetes), arrow-points from the stone period of Japan, and a number of petrefactions.

It would have led too far to mention all the diseases for which these various remedies have been used; but at a future occasion, should we find space to continue the *résumé* of the contents of the Japanese Pharmacopœia, we shall add the necessary therapeutical remarks, when deemed of interest.

ELIXIR OF MONOBROMATED CAMPHOR.*

BY M. DAMBIER.

The complete insolubility of monobromated camphor in water appears to forbid the idea of administering it in the form of a syrup. But in consequence of such a preparation being occasionally ordered in prescriptions, the author was induced to make some experiments that have led him to recommend an alcoholic syrup. 40 grams of powdered sugar are dissolved by the aid of heat in 60 grams of 56° alcohol, the solution filtered if necessary, and then 50 centigrams of monobromated camphor are dissolved by the aid of heat in the clear liquor. The preparation can be flavoured to suit the taste.

The readiness with which camphor and bromine combine to form a definite compound suggested to the author to try the experiment of effecting the combination in the presence of the syrup. The result, pharmaceutically, was not satisfactory, but the author states the therapeutic effects obtained with this syrup were such as to encourage him in prosecuting the investigation; at the same time he published his method of operating. 0·204 gram of camphor was heated until dissolved in a flask with about 8 grams of 90° alcohol, and into this 0·392 gram of bromine was poured, drop by drop. 100 grams of simple syrup were then added gradually, with agitation after each addition. The syrup became slightly turbid and reddish yellow towards the end of the operation. Upon applying heat the colour disappeared as the temperature rose, until at boiling it was perfectly limpid and colourless. As it cooled, however, it became slightly opalescent, and flocks of camphor floated on the top; upon agitating, these easily mixed with the rest of the liquid, or the liquid became again limped upon reheating it. The author seems to think that in this mixture there is no combination between the bromine and camphor, but that probably the camphor is held in solution by hydrobromic acid.

* Abstract from paper in *L'Union Pharmaceutique*, vol. xvii., p. 354.

A NEW APPLICATION OF THE DIALYTIC PROCESS.*

BY R. ROTHER.

In the article on "The inverse synthesis of the so-called tasteless iron compounds" (*American Journal of Pharmacy*, April, 1876), the writer pointed out the important fact that in particular cases of colloidal compounds the endosmotic current is the most prominent feature of the movement. On such occasions the inward course of the outer liquid appears to be the only force of the phenomenon, since exosmosis prevails so feebly that practically its effect reduces to zero. The rapidity of the endosmotic current gives promise that a new development of this interesting and remarkable process will lead to great advantages in numerous and important pharmacal operations. This peculiarity presents a new means of concentrating solutions where the absence of heat is not only desirable, but often imperative. In its practical bearing this method of transcendental filtration presents a wide range of application, which must be classified, however, as entirely distinct from the present sense, and the theoretical action in which the process is usually considered. The residue, technically termed the diffusate, is, according to the original idea of this process, a solution of the diffused substance. The residue of the new modification differs from the diffusate proper in the particular that it practically contains nothing originally introduced into the dialyser, but that it simply represents that portion of the original outer liquid which refused to pass inwards through the membrane. Therefore, according to the new construction, the process resembles filtration more closely than its primitive process from which it is derived. In some instances it is even more rapid than ordinary filtration. Absorption in this operation corresponds with volatilization in the usual method of concentration by the means of heat. As the action of heat produces undesirable and often destructive changes in many substances, even at the lowest possible degree, the process of dialytic filtration must naturally commend itself on all such occasions, where its application is available. If the point of a parchment dialysing cone containing a concentrated solution of a strongly colloidal substance be immersed in a dilute solution of a crystalloid, the superabundant water of the latter is more or less rapidly absorbed into the dialyser, leaving, after due action, the solution of the crystalloid in its utmost concentration. It is possible that this process may become useful in the industrial production of alkaloids, where in the usual method large volumes of water must be expelled by means of heat, the action of which, in many cases, greatly reduces the yield by the generation of inert modifications or worthless disruption products. This process, with its accompanying apparatus, is more congenial to the surroundings of modern pharmacal laboratories in which the routine is less interspersed with the manipulation of distrustful retorts, precarious capsules, and fuming crucibles of the empiric era. It would be hardly proper to designate this process by dialysis, since that term specifically denotes an operation not exactly similar. Absorption does also not strictly convey the true meaning of its action; however, in case the new process should prove itself of such general value as the first indications seem to promise, a more appropriate term will readily be found.

The Pharmaceutical Journal.

SATURDAY, FEBRUARY 17, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE METRICAL SYSTEM IN PHARMACY.

THE fact that of all civilized nations those speaking the English tongue stand alone in their attitude towards the Metric System of Weights and Measures appears to be just now forcing itself upon the attention of the United States public, and especially upon our pharmaceutical brethren in that country. The subject appears likely to come before Congress in the present session, in connection with a petition that has received the signatures of upwards of eleven hundred leading men in all professions, so that the publication of the report of a Committee discussed by the American Pharmaceutical Association at its last meeting is very opportune. And as the movement that appears to be gathering force rather rapidly on the other side of the Atlantic cannot be without influence in this country, it may be as well to glance briefly at what is there taking place.

The report above referred to recommended among other courses an appeal to Congress for compulsory legislation on the subject, but the speakers in the discussion seem to agree that for this step the time had not yet arrived, and that it would be necessary first to further educate and familiarize the public mind as to the nature of the system; it was therefore referred to the Committee to report again at the next meeting. But some of the other parts of the report indicated the directions in which it was thought desirable that work should be done. It was proposed to appoint a standing committee of three members, whose duty it should be to invite the cooperation of other associations; to request authors of papers to adopt the metric system or else to add the metric equivalent to ordinary statements of weights and measures; to secure the teaching of the metric system and its inclusion among the subject matter of examination for admission and for graduation in schools of pharmacy; and to urge upon chemical and pharmaceutical manufacturers to aid by adding metric equivalents to the weights stated on the labels of their original packets and vials, and adopting at their earliest convenience metric instead of avoirdupois quantities in putting up their products in small original packets and vials. The report also stated that the method already adopted in the most advanced pharmacopœias was to employ parts by weight only, and that this plan had the advantage of being adjustable to any system and proportion of weights.

Of course the arguments are not all on one side, and many objections have been started that will have to be met. In fact, in 1870 the national convention for revising the United States Pharmacopœia gave definite instructions to the Committee to which it entrusted the work to abandon measures of capacity in the Pharmacopœia, and to express the quantities in all formulæ, "both in weight and in parts by weight." But the Committee found that this would "involve changed proportions in almost every formula" and that the carrying out of the necessary experiments "would entail so much expenditure of time, labour and cost," that it decided to disobey its instructions as impracticable. Thus this preliminary project, designed presumably to facilitate the introduction of the metric system, fell to the ground.

In order to attempt to combat the tendency of persons long accustomed to write or read prescriptions for liquids by measure to over-estimate the difficulty attending the use of terms by weight, Professor MAISCH, in an article written for the *Philadelphia Medical and Surgical Reporter*, and copied into this Journal (before, p. 352), pointed out that any difficulty was easily over come by bearing in mind the specific gravity of the liquid, and that by taking the ounce as 30 grams and multiplying that number by the specific gravity a result is obtained in grams of the metric system sufficiently approximate for practical purposes, the variation being quite within the limits of error in ordinary measurements of liquids. The conversion of solid grains into grams might also be effected with sufficient exactness, he argues, by dividing by 15.

The practicability of this suggestion has been disputed by Dr. BLODGETT, of Boston, on the ground that it would be a burden in prescribing and that probably few doctors would care to adopt so laborious a system. He adds that the impression most physicians follow in prescribing is that of the volume of the liquid, and asserting "that this principle finds a ready and simple application in the metrical system as employed in the larger universities and hospitals of Europe, where this system is in use, as well as in the hands of scientific men generally of those countries," expresses regret that Professor MAISCH has overlooked this fact.

Professor MAISCH, in a long reply read before the Philadelphia College of Pharmacy at its last meeting, admits that measures are at the present time more frequently employed than weights in chemical assays, but demurs to the discussion as to the use of the metric system in prescriptions being mixed up with the manner in which that system is employed in the arts and sciences. The latter part of Dr. BLODGETT'S allegation he completely denies, and proceeds to prove his proposition, that "the pharmacopœias of continental Europe and the prescriptions of physicians of those countries express all quantities by weight only, whether the material directed be solid or liquid." This he does very successfully by quotations from European pharmacopœias and standard works on pharmacy. The same proposition is true in reference to Mexico and Cuba, whilst the States of Southern America, having no pharmacopœias of their own, adopt those of other nationalities.

It is obvious that before much progress can be made in impressing Congress an agreement must be arrived at as to what is to be asked for. We learn that the movement has two very strong opponents in Washington, Professor HENRY, who is at the head of the Smithsonian Institute, and Professor PIERCE, who is chief of the United States Coast Survey. Moreover, the Chairman of the House of Representatives Committee on the subject is said not to have his interests enlisted on the side of the metric system. But as this gentleman is described with characteristic bluntness by Dr. SQUIBB as being put into that position because there was no other place for him, the place he wanted not being available, it is to be hoped that something may "turn up" more consistent with his tastes.

THE BRISTOL PHARMACEUTICAL ASSOCIATION.

THE Honorary Secretary of the Bristol Pharmaceutical Association has just issued an announcement of arrangements which not only must be received with satisfaction by its own members, but is likely to command the envious regard of those of kindred societies. The Bristol Library and Museum will be remembered by those who attended the Pharmaceutical Conference of 1875 as the institution in which the meetings were held; the Library contains more than 40,000 volumes of scientific and general literature, and the Museum ranks high amongst provincial museums. By the courtesy of the Council arrangements have been made under which all Members and Associates of the Bristol Pharmaceutical Association will be at liberty, upon showing a ticket, to study everything within its walls, with the exception of the contents of the news room. As, however, they will not be able to remove anything from the premises, an effort is being made to collect a small number of works on professional subjects to be placed in the same room, but to be available for home study. A collection of pharmaceutical objects is also being formed in the Museum.

As lectures upon chemistry and botany and laboratory instruction upon practical chemistry are now presented at the University College, Bristol, and at the Trade and Mining School, the Council of the Pharmaceutical Association does not itself provide or recommend any special course, but encourages students to attend those already provided by the offer of several prizes for competition during the coming summer.

The Council is also able to announce three occasional lectures to be delivered in the Inner Library of the Bristol Museum. The first of these, on "Chemical Synthesis," by Dr. W. A. TILDEN, was delivered on Friday of the present week, the second by Mr. H. S. THOMPSON, of University College, Bristol, on "Atoms and Particles," is to be delivered on the 16th of March, and the third by Dr. E. A. LETTS, of the same College, on the 20th of April.

MEETING OF THE TRADE AT EDINBURGH.

IN accordance with an announcement that has recently been circulated a meeting of pharmaceutical chemists and chemists and druggists was held on Tuesday evening, under the auspices of the Chemists and Druggists' Trade Association, at 5, St. Andrew's Square, Edinburgh. The objects of the meeting were to place before the chemists and druggists of the country a statement of the claims of the Association upon them, to urge the necessity for combination, as well as to consider whether a North British Branch of the Association should be formed and what support should be given to the Association from that district. The chair was taken by Mr. GEORGE BLANCHARD (of RAIMES, BLANCHARD and Co.), and we are informed that the number attending the meeting was between twenty and thirty, including deputations from other towns. The chief speaker was Mr. BARCLAY, of Birmingham, and the proceedings, which do not seem to have been very animated, were concluded within an hour. Reference was of course made to the correspondence published in the report of the Council's proceedings last week, and as will be seen by Mr. BARCLAY'S letter on another page, the assumed misconstruction of Mr. HAYDON will be explained by him next week.

SCHOOL OF PHARMACY.

THE Courses of Lectures on Chemistry and Pharmacy, and Materia Medica and Botany, in connection with the Pharmaceutical Society's School of Pharmacy, 17, Bloomsbury Square, will recommence on Thursday, March 1st. Students who have but a limited time at their disposal will find the ensuing five months to be a favourable time for studying at the School; for between the 1st of March and the 31st of July they will have the opportunity of not only attending in the Laboratory and at the usual Courses on Chemistry and Pharmacy and Botany and Materia Medica, but also the Summer Course on Systematic and Practical Botany, at the Royal Botanic Society's Gardens, in Regent's Park.

THE PHARMACY OF PRECIOUS STONES.

IT was only a few months since that Europeans who followed the trial of the Gaikwar of Baroda for attempting the life of the British Resident at his court, had an opportunity of speculating as to the poisonous properties that resided in diamond dust, which it was alleged was one of the means by which he hoped to attain his end. According to the *Pall Mall Gazette* this potentate, who has now retired from business, is still pursuing his researches upon the virtues of precious stones; but this time, as the experiments happen to be made upon a person for whom he has more love—himself—the gem is varied. Having a very high opinion of the medicinal virtues of the ruby his ex-highness is said to be now attempting to repair his constitution by a course of what possibly, in a lithic Pharmacopœia, might be termed Pulvis Rubini, which he takes sprinkled over cakes. Experiments are also being made with the powders of other precious stones, incorporated with confectionery, possibly as Trochisci. It is not surprising to learn that this kind of pharmacy, which is carried out by native cooks, is rather expensive. It is to be hoped, however, that the article supplied is of the "nature, substance, and quality" demanded by the purchaser, though in this country the presence of a compound of alumina in either food or drug would be certified as evidence of adulteration by some public analysts.

ETHER TIPPLING.

THE *Lancet* reports that the greater capability of ether to intoxicate at the same cost as compared with alcoholic liquids, is favouring its consumption in certain parts of the North of England, where a large amount of ether drinking at present goes on.

MEDICINE IN BURMAH.

IT is stated that in Burmah surgeons and surgical operations are unknown. Physicians, however, are divided into three classes,—those who treat diseases with mineral or vegetable medicines; those who trust chiefly to diet; and doctors who proceed by spells and incantations. Usually the "physician" is paid so much a visit, the fee ranging from eight annas (1*s*.) to five rupees (10*s*.). Sometimes, however, the system of "payment by results" obtains, and the Burmese witch doctor thus shakes hands with the South Kensington Science Teacher.

THE SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A MEETING of the above Association will be held at 17, Bloomsbury Square, on Wednesday evening, February 28th, 1877, at eight o'clock (instead of on Thursday, the 22nd inst.), when a paper will be read by Mr. C. J. MEAD, on "The Radiometer—what it is, and a few facts connected with it."

MR. JAMES BAYNES, jun., Pharmaceutical Chemist, has been appointed Public Analyst for Hull.

Transactions of the Pharmaceutical Society.

NORTH BRITISH BRANCH.

The fourth meeting of the present session was held in the Society's rooms, 119A, George Street, Edinburgh, on the evening of Wednesday, January 31. Mr. William Gilmour, President of the Branch, in the chair. A paper was read: "On Incompatibility as Applied to Medicines," by Dr. F. W. Moinet, Lecturer on Materia Medica, Edinburgh School of Medicine. At the conclusion of the paper a discussion took place, the chairman, Messrs. J. B. Stephenson, Howie, McAlley, and Mackay taking a part.

Mr. J. B. Stephenson referred to a case recorded in the *Pharmaceutical Journal* some time ago, illustrating the incompatibility of strychnine with alkalies, and mentioned that he had recently met with a similar case in a mixture which he had dispensed containing tincture of nux vomica and liquor bismuthi. In both cases the strychnine had been precipitated, and the last two or three doses, containing the whole of it, had caused decided symptoms of strychnine poisoning. He (Mr. Stephenson) had made it a rule, since this happened, to label every mixture containing these ingredients—"Shake the bottle."

Mr. W. L. Howie said that he had listened with much pleasure to Dr. Moinet, and would just allude to his remarks on lead and opium lotion. The doctor had said that "both the new substances formed had medicinal values," and he (Mr. Howie) feared this remark might lead some dispensers to omit filtration which he knew was a common practice. Such a lotion made with acetate of lead and laudanum would contain in solution acetate of morphia and excess of acetate of lead, while meconate of lead would be precipitated. He thought it desirable that the lecturer should indicate whether in his opinion this meconate of lead should be filtered out or allowed to remain in the lotion.

Dr. Moinet replied that because a medicinal agent was chemically insoluble, it did not follow that when taken into the stomach or applied externally it was physiologically inert. Very many such substances were soluble in the fluids of the stomach or were absorbed by the skin and the specific effects produced. He illustrated this by reference to tannate of iron, and this meconate of lead was another illustration. Yet the tannate was an extremely inelegant mode of exhibiting iron and should be avoided, since so many other salts were available; and while he considered meconate of lead in the lotion in question had medicinal value, he thought it would be better to so arrange the proportion of ingredients that no precipitate would be produced.

The Chairman (Mr. Gilmour) remarked that Dr. Moinet's paper was not only appropriate but practical and as much adapted to a medical audience as to a pharmaceutical one—for, considering the three different classes into which the doctor had divided the incompatibles, it was not an uncommon thing to meet with instances of each in prescriptions brought to the dispensary. In the case of one of the mechanical mixtures, for example, and especially of the mixtures that were even at the best disagreeable and ungainly, the endeavours of the dispenser to make it appear as elegant as possible, not only frequently ended in failure, but perhaps produced a mixture which, if the prescription were presented at another establishment, could not be imitated, and this not unfrequently was the cause of a little annoyance between customer and dispenser. Referring to the class of chemical incompatibles, Mr. Gilmour remarked that one of the most difficult points which the dispenser had often to determine as to the changes which took place in such mixtures was, Were these changes foreseen and intended by the prescriber? As an instance he referred to a prescription which he had frequently dispensed and which quite belonged to a class specially referred to by the doctor, viz., iron and certain vegetable infusions, only this prescription was tincture of iron and tannic acid, the product being a compound chemically and physically like writing ink. The principal difficulty here lay in the unseemliness of the mixture, but the case was even more grave and difficult with regard to the mixture referred to by Mr. Stephenson, where strychnine was precipitated by the action of liquor bismuthi on nux vomica. In this respect, he (Mr. Gilmour) fully indorsed Dr. Moinet's sentiments with regard to the responsibility both of prescriber and dispenser. It was not in the endeavour to avoid any of this responsibility, or out of any querulous spirit towards the medical profession that he had touched upon these points, but simply to show some of the difficulties which the conscientious and faithful dispenser had daily to meet and overcome. Mr. Gilmour briefly alluded to the third class of incompatibles where the number of ingredients made it difficult to note the chemical changes, or to imagine what the therapeutical action might be.

Mr. Mackay remarked that in his experience of prescriptions he had noticed a marked difference between those of English and Scotch practitioners. In the composition of his prescription, the English medical man studied taste and appearance as well as effect, while, on the other hand, the Scotch paid most attention to the latter; but he (Mr. Mackay) was glad to notice a marked improvement in this respect.

Dr. Moinet confirmed Mr. Mackay's statement in this respect, and in noticing Mr. Gilmour's remark about the number of ingredients, he stated that a prescription containing fifteen different articles had lately been brought under his notice.

On the motion of Mr. Stephenson, seconded by Mr. Mackay, a vote of thanks was awarded to Dr. Moinet for his interesting and instructive paper.

Provincial Transactions.

GLASGOW CHEMISTS AND DRUGGISTS' ASSOCIATION.

The fourth meeting of the session in connection with the society was held in the Manager's Library of Anderson's University. Mr. Daniel Frazer in the chair. After the usual preliminary business had been disposed of, the chairman called upon Dr. A. T. Machattie, F.C.S., etc., who delivered the second lecture of his short course on "Modern Chemistry."

After a short reference to the subject of his former lecture, more particularly with regard to modern views of the history of the earth, the lecturer proceeded to give a general sketch of the characters of the elementary bodies found on the earth, and already, to some extent at least, in the other members of the solar system. It was shown that various sciences are in some instances more interested in certain groups of elements than in others. Thus mineralogy must take cognizance of all. Geology is more occupied with those which occur widely diffused and in large quantity, as hydrogen, oxygen, carbon, silicon, sulphur, phosphorus, potassium, sodium, calcium, magnesium, and aluminum. Botany and zoology are again more interested with the characteristic elements of living beings, and so on. Some peculiar features of the principal elements of living beings viz.: carbon, hydrogen, nitrogen, oxygen, sulphur, and phosphorus were then referred to, as for instance, nitrogenous compounds, their instability, as evidenced in the protein group; their action on the animal system, as in the case of the alkaloids, prussic acid, etc.; their extreme decomposibility, as in guncotton, fulminates, nitro-glycerine, iodide and chloride of nitrogen, etc., etc.; their atomic complexity in the protein group, as affording immense possibilities of internal atomic change, without alteration of actual composition, thereby rendering these nitrogenous compounds eminently fitted for the various and constant changes in the organs of living beings. Under this head reference was made to the light which Graham's discovery of the colloid and crystalloid conditions of matter threw on many physiological problems, and a short description given of what was understood by the dynamical and statical conditions of matter. After a sketch of the general uses of the principal elements in the mineral, vegetable, and animal kingdoms, the lecturer concluded by stating that, at the last lecture, more attention would be paid to the individual characters of the elements than to their functions in nature.

At the close of the lecture, the President made a few remarks, and after some intimations had been made by the secretary the meeting was brought to a close.

LIVERPOOL CHEMISTS' ASSOCIATION.

The members of this Association held their thirteenth Conversazione on the 18th of January, at the Royal Institution, Colquitt Street. There was a large attendance, more than four hundred members and visitors (principally ladies) being present. A very excellent and interesting evening's entertainment was provided, and it has been pronounced the most successful conversazione yet held by the Association.

After the reception of the visitors by the President and Council, half an hour was devoted to a musical entertainment, which was ably rendered by some volunteers under the direction of Mr. John Hodgson. After this there was a promenade in the museums, where numerous objects of scientific interest were exhibited, to which the following gentlemen contributed:—Several members of the Microscopical Society of Liverpool; Mr. A. H. Samuel had charge of an exhibition of electrical instruments and appliances, and he ably explained the various experiments performed; Mr. G. F. Chantrell exhibited the patent electric pen; Mr. E. Davies, F.C.S., the spectrum of gallium, the new element; Mr. C. H. Stearn, an improved Sprengel pump (to which was attached a radiometer), invented by himself; Mr. J. T. Armstrong, F.C.S., a model geyser, and experiments illustrating ground air currents; Dr. Symes, specimens of toughened glass, the process of manufacture of which he popularly explained; Mr. Anden practically illustrated the art of chromo-lithography; Mr. A. H. Mason, F.C.S., exhibited vortex rings; Messrs. Symes and Co., chemical apparatus, etc. Messrs. Doulton and Co., art pottery; Messrs. Elkington and Co., works of art in electro-plate and bronze; Messrs. Abraham and Co., scientific instruments and electrical appliances; Messrs. Brown, Bell, and Barnes, photographic novelties; Messrs. Chadburn and Son, scientific instruments, graphoscopes, stereoscopes, etc.; Messrs. Austin and Co., magnetic indicators; Messrs. Fearnall and Co, model of the Minerva printing machine.

At nine o'clock the chair was taken in the lecture theatre by the President, Mr. A. H. Mason, F.C.S., who welcomed the guests in the name of the Council, and thanked those gentlemen who were assisting, for their liberal and voluntary aid. He spoke of the objects of the Association, and the work it had accomplished. He thought Liverpool was behind other large towns in her provision of such entertainments, and the large attendance present assured him that if the different learned societies of the town combined, and a substantial annual grant was made from the corporate funds, a highly scientific Conversazione might be held in some much larger building, which would be looked forward to by many by whom it would be appreciated. The President then introduced the lecturer, Mr. W. E. Bickerdike, F.C.S. (of Church), who delivered a popular chemical lecture on

"The Atmosphere," illustrated by numerous experiments, of which the following is a syllabus:—Introduction—Nature of the Atmosphere—An Ocean of Gas—Coloured Gases—Weight and Elasticity of the Atmosphere—Balloon Ascent—Principle of the Air Pumps—Barometer—Air, a vehicle for Sound—Organ Pipe with Hydrogen—Formation of Cloud and Dew—Chemistry of the Atmosphere—Composition of Air—Nitrogen Gas and its Properties—Oxygen Gas—Combustion—Burning of Metals—Spontaneous Combustion—Nature of Respiration—Carbonic Acid Gas—Vitiated Air—Trade Winds—Breathing of Plants—Ventilation—Healthy Dwellings—Conclusion. The experiments all proved most successful, and an admirable lecture was delivered; after which Mr. E. Davies, F.C.S., moved, and Dr. Nevins seconded, a hearty vote of thanks to the lecturer, which was carried with great acclamation.

During the promenade and reception the band of the 1st L.A.V. performed a selection of popular music.

The eighth general meeting was held at the Royal Institution, on the 1st inst. The President, Mr. A. H. Mason, F.C.S., in the chair.

Mr. Thomas Garside, F.C.S., read a "Report on a New Method for the Examination of Mixtures of Methylic and Ethylic Alcohols."

The method was suggested in the *Comp. Rend.*, and Mr. Garside had applied it successfully for the detection of methylated spirit in wood naphtha. He believed the latter was often adulterated and had found that an admixture of 10 per cent. rendered wood naphtha quite unfit for some of the purposes for which it was required. The process was practically demonstrated to the audience.

A discussion followed in which Messrs. Davies, Abraham, the President, and others took part, and an unanimous vote of thanks to Mr. Garside closed the proceedings.

MIDLAND COUNTIES CHEMISTS' ASSOCIATION.

The annual soirée of the above-named Association was held on Tuesday, the 30th ult., in the Town Hall, Birmingham, and there was a brilliant assemblage. The noble hall, which has just undergone complete redecoration internally, could scarcely be seen to greater advantage, the orchestra being beautifully decorated with flags and shrubs in pots, which relieved the scarlet and gold uniforms of a military band.

Hitherto, one of the attractions of the evening has been an exhibition of objects and works of art, illustrations of various processes of manufacture, etc. But by resolution of the Committee the exhibition was this year withdrawn, and every energy was concentrated upon producing a ball upon a grand scale. These efforts were rewarded by a select party of about 300 ladies and gentlemen, who spent a very pleasant evening, producing a good surplus to the funds of the Association.

LEICESTER CHEMISTS' ASSISTANTS AND APPRENTICES' ASSOCIATION.

The half yearly meeting of the members of the Association was held at the Rooms, Halford Street, on Tuesday, the 30th January last. A report was read in which the Committee stated that although unable, as upon some former occasions, to boast of distinctions won at Bloomsbury Square, the work accomplished had been thorough, there having been exhibited a decided desire on the part of the members to become proficient in the various branches of pharmaceutical education. The usual examinations had been held. The marks obtained indicated that the efforts of the teachers had been well appreciated. To excite special interest and diligence, three prizes had been offered for competition, the successful competitors being Messrs. Lewitt, Mason and Charlesworth. The number of ordinary members upon the books was reported to be thirty-one, and honorary, thirty-four.

Four special lectures had been delivered, one by Mr. F. T. Mott, F.G.S., one by Mr. Wells, and two by Mr. J. J. Edwards. The classes conducted by Messrs. Clarke, Hammond, Raynor, Garrett and Edwards had met thirty-eight times. The average attendance during the session had been ten, which was an improvement upon the past. The thanks of the Committee were tendered to Mr. Raynor for his presentation of microscopic slides.

The Report was unanimously adopted.

After the transaction of routine business the members proceeded to elect the committee for the ensuing session, with the following result: Mr. W. Hammond, President; Mr. T. C. Raynor, Vice-President; Mr. J. Garrett, Hon. Secretary; Mr. W. B. Clark, Treasurer; Messrs. C. B. Lomas, W. B. Baron, W. Mann.

The Treasurer's Report showed that the receipts during the half year had amounted to £22 19*s.* 7*d.*, and the expenditure to £11 15*s.* 8*d.*, leaving a balance in hand of £10 0*s.* 3*d.*, in the place of a deficiency of £1 3*s.* 8*d.* that existed at the commencement of the half year.

A programme of lecture classes, etc., extending to the end of July next was also presented.

The opening meeting of the seventeenth session was held on Tuesday evening, February 6, when the President, Mr. Hammond, delivered his inaugural address, at the close of which a unanimous vote of thanks was accorded to Mr. Hammond. Papers were then read by the teachers in chemistry, botany and pharmacy, on their respective subjects. A most excellent address was also given by Mr. W. Clark, and varied readings by Mr. Mann.

Proceedings of Scientific Societies.

NEWCASTLE-UPON-TYNE CHEMICAL SOCIETY.

At a general meeting of the above Society, in the theatre of the College of Physical Science, January 25, 1877, the President in the chair, the following paper was read by the Secretary:—

THE RETARDATION OF CHEMICAL REACTIONS BY INDIFFERENT MATTERS, ESPECIALLY GLYCERINE.

BY DR. G. LUNGE.

The observations described below were occasioned by a number of experiments made on behalf of the Swiss Government, for the purpose of discovering a more reliable method of "obliterating" postage stamps than those hitherto in use. Among the stamping inks I prepared with that intention, there were several with a basis of glycerine, and I soon observed that, if any acids were present in such mixtures, they comported themselves differently to colouring matters than if the same acids were used merely in dilution with water. This led me to make some experiments of a simpler nature, and, although I have been prevented by want of time from following them up very far, and from extending them to that point which a true scientific treatment would require, I venture to lay them in that incomplete state before this society in the hope that they may not be found quite uninteresting, and that perhaps someone else will take the matter up with more leisure than I have had at my command.

My principal experiments were made upon the behaviour of wrought iron (in the shape of wire nails) towards a mixture of glycerine and hydrochloric acid. The hydrochloric acid contained 26·1 per cent. of real HCl, and was mixed with an equal volume of pure syrupy glycerine. Check experiments were always made with the same hydrochloric acid, mixed with the same volume of water. Fuming hydrochloric acid can be mixed with glycerine easily in every proportion; nor does it act upon the latter chemically, at least not at the ordinary temperature, at which all my experiments were performed. Although the formation of monochlorhydrine would seem to be excluded by the very conditions of the experiment, I made sure of it by titrating the mixture before use, and, as may be imagined, I found its percentage of HCl exactly as calculated from the dilution, just as if the diluting fluid had been water instead of glycerine. The acid diluted with glycerine in many cases behaves precisely like that diluted with water; for instance, towards sodium carbonate, calcium carbonate, silver nitrate, sodium hyposulphite, solution of chloride of lime, litmus, etc.; at least, no difference could be noted in the preliminary tests, and it thus seemed unnecessary to make quantitative trials. A difference was, however, noted in the case of paper stained blue by ultramarine. Whilst a strip of it in the acid diluted with water is beginning to be bleached ten seconds after immersion, and has become perfectly white in thirty seconds, another strip, dipped in the acid diluted with glycerine, only begins to be bleached after the lapse of forty-five seconds, and is only thoroughly whitened in four minutes.

The difference is, however, much more decisive in the action of the two acids upon iron or zinc. A bright wire nail (weighing 0·4927 grm.) completely dissolved in 6 c.c. of the acid diluted with water in ten hours' time, apart from a small carbonaceous residue. On the other hand, a nail (weighing 0·4875 grm.) immersed in 6 c.c. of the acid diluted with glycerine weighed—

After 24 hours, 0·4200 = 86·2 per cent. of the original weight.
„ 3 days, 0·2764 = 56·6 „ „
„ 6 days, 0·1405 = 28·8 „ „
„ 14 days, 0·0065 = 1·3 „ „

The solution still contained free acid, and behaved in every respect like an ordinary acid solution of ferrous chloride; for instance, towards precipitating reagents.

In another experiment, there were immersed:—

(*a*) A nail weighing 0·385 grm. in 20 c.c. of acid diluted with water.

(*b*) A nail weighing 0·450 grm. in 20 c.c. of acid diluted with glycerine.

The evolution of gas (similarly to the previous cases) was much stronger in the case *a* than in the case *b*. After the lapse of three hours both test tubes containing the iron and acid mixtures were closed by gas delivery tubes, and connected with graduated cylinders inverted over a pneumatic trough. Eighteen hours later there had been collected from the tube *a* 74 c.c. of hydrogen gas, whilst the iron in it was completely dissolved. The experiment *b* was interrupted forty-four hours after the connection with the graduated cylinder, when only 52 c.c. of gas had been collected, and more than half of the nail was still left undissolved.

The action of the two acids on granulated zinc was much more rapid, but still showed a marked difference. 1 gram. of zinc, with 20 c.c. of acid and water, evolved 200 c.c. of gas in 1½ minutes; 1 gram of zinc with 20 c.c. of acid and glycerine took eight minutes to produce the same result. Other experiments, always with a similar result, were made with iron borings and hydrochloric acid; also with iron borings and sulphuric acid, diluted in one case with four volumes of water, in the other with four volumes of glycerine.

The cause of the retardation of the action upon metals in the case of acids diluted with glycerine can hardly be a purely chemical one, since on the one hand the glycerine is not acted upon, and since, on the other hand, it does not itself act either upon the reagents or upon the product of the reaction. The latter (ferrous chloride) is easily soluble in glycerine, as was proved by independent experiments, and it cannot, therefore, be presumed that the case is analogous to the insolubility of some metals in concentrated acids. Probably the real cause is—at least, partly—the viscosity of the glycerine, which is perfectly apparent even in the mixture with acids. The gas bubbles cannot liberate themselves very quickly from the iron, and thus prevent the contact between it and the acid. This assumption is supported by the fact, that the attack of acid upon iron is much more weakened by dilution with a solution of gum arabic than with pure water, as I found on trying it. But this explanation does not hold good for the retardation of the action of hydrochloric acid upon ultramarine, as well as in several other cases observed by me, and the following experiments do not in any way seem to be compatible with it. If fuming hydrochloric acid, diluted with the same bulk of water, be mixed with a little lamp-black (moistened with a drop of alcohol, to make the acid wet it), and if iron nails are immersed in the mixture, they are so little acted upon, that the evolution of gas is hardly perceptible at all; twenty-four hours after the nail looks exactly as it did at first. But if the mixture be now thrown upon a filter, and the same nail be placed in the acid running through the filtering paper, a strong evolution of gas commences immediately, and the nail is dissolved very soon.

The following quantitative experiments were made with a mixture of 50 parts of glycerine with 30 parts of fuming hydrochloric acid, and 3 parts of lamp-black. A nail weighing 0·536 grm. produced only after some hours a few minute bubbles of gas, and showed the following weights:—

After 3 days, 0·4780 = 89·2 per cent. of the original weight.
„ 6 days, 0·4001 = 74·6 „ „
„ 14 days, 0·2575 = 49·0 „ „

In another experiment, a nail of 0·5766 grm. weighed,

After 3 days, 0·5124 = 88·8 per cent. of the original weight.
„ 6 days, 0·4440 = 77·0 „ „

The experiment was then interrupted by filtering the mixture. In the filtrate, 92 per cent. of the acid could be proved analytically; the remaining 8 per cent. might easily have been lost by incomplete washing of the slimy carbonaceous residue; but in any case there was far more acid in the filtrate than sufficient for dissolving the nail, and, in fact, the same placed in the filtrate at once caused an evolution of gas, certainly only at a moderate rate, as explicable by the presence of glycerine, and by the large dilution with the washing water. Zinc behaved in exactly the same way towards the same mixture.

It does not seem impossible that this retarding action of indifferent substances may find a useful application, both for moderating chemical reactions in scientific operations and in technical operations on the large scale. It would give me great pleasure if this subject were pursued further by some one interested in it, and if a satisfactory explanation of that phenomenon were suggested.

Mr. J. W. Swan made some remarks on the behaviour in treating of a mixture of alcohol and glycerine, and promised a further communication on the subject.

The discussion of Dr. Lunge's paper was postponed till the next meeting.

Mr. B. S. Proctor exhibited a new form of washing-bottle for gases.

PARIS SOCIÉTÉ DE PHARMACIE.

A meeting of the above Society was held on the 8th of January, under the presidency of M. Marais.

M. Stanislas Martin presented to the Society a specimen of Mutambo bark, which he stated was much used in Brazil, and one of Timbo leaves.

A note was presented from M. Beniot, on "The Testing of Chlorate of Potash," the process being based on the conversion of protosalts of iron into persalts by chlorate of potash in the presence of strong hydrochloric acid.

M. Planchon presented a specimen of Hoang Nau, said to be prescribed by the Chinese missionaries against hydrophobia and leprosy. M. Planchon remarked that the bark was very bitter, and had many points of resemblance to false angustura bark; he thought it was probably derived from a strychnaceous plant.

A report of a committee was read proposing that the prefect of the department should be requested to name four streets in Paris after the celebrated pharmacists, Serullas, Gaudichaud, Pelletier, and Caventou.

M. Poggiale gave a sketch of some of the memoirs that had been recently presented to the Academy of Sciences.

Croton Oil Pencils.—M. Limousin read a note upon the employment of croton oil pencils in the treatment of scurf of the head. The pencils are prepared according to the following formula:—

Cacao Butter.	1 part
White Wax	1 part
Oil of Croton	2 parts

Melt the cacao butter and wax by the heat of a water-bath in a small glass flask; then add the croton oil and carefully cork the flask. When the mixture commences to solidify pour it into moulds and put in a cool place.

The pencils are small cylinders, 8 or 9 millimetres in diameter. To prevent volatilization of the acrid principles of the oil they are either covered with pure tinfoil or kept sheltered from the air in metallic cases. It was stated that although the pencils only contain 50 per cent. of croton oil, the revulsive action is much more energetic than when the oil is applied in its natural state, whilst the locality of its action can be more exactly limited.

Parliamentary and Law Proceedings.

Poisoning by a Vermin Killer.

The Deputy Coroner for Brighton has held an inquest at the Sussex County Hospital, on the body of Thomas Wood, who committed suicide by poisoning himself. The landlady of the Rock Inn deposed that she heard a noise in the deceased's room, and on going up found that the door was locked on the inside. The door was broken open, and deceased was found undressed and in bed, and appeared to be in convulsions. After waiting a little while, and finding that he did not get any better, Dr. Scatcliffe was sent for, who ordered his removal to the hospital. The glass and powder produced witness found on the washstand. A letter from deceased to his parents was found, stating his intention of committing suicide, and he had made an entry of his own death in his diary.

Mr. T. Jeeve, chemist, 88, St. James's Street, deposed that he sold a threepenny packet of Battle's vermin killer to the deceased. It contained strychnine.

William Field, senior pupil at the hospital, said that he saw the deceased when he was brought to the institution, and in reply to witness he said he had taken the strychnine in mistake for a seidlitz powder.

Mr. H. Neale Smith, the house surgeon at the hospital, stated that the deceased died about an hour after his admission. Shortly before his death he complained of intense pain in the stomach, and died in a spasm. From a *post-mortem* examination that he had made, he found that the whole of the organs—with the exception of the lungs, which were slightly congested—were healthy, and from the symptoms witness was of opinion that death resulted from poisoning by strychnine.

The jury returneda verdict, "That the deceased committed suicide, but that there was not sufficient evidence to show what was his state of mind."

Poisoning by Santonin.

An inquest was held at Manchester, on Thursday, Feb. 8, by the City Coroner (Mr. E. Herford), on the body of John M'Guinness, aged five years and three months.

The mother said the deceased had been troubled with worms, and on Saturday night, about 10 o'clock, she sent an elder boy to Mr. Sherratt, druggist, 222, Queen's Road, for some worm lozenges. He brought back the lozenges and a powder. Witness was lying on the sofa and the deceased was given the lozenges by his brother, Shortly after, witness went out of the house on an errand. and on returning after an absence of five minutes she found the deceased very ill. A doctor was sent for: The child died in about half an hour afterwards.

Thomas M'Guinness, 17 years of age, son of the last witness, said his mother sent him to Mr. Sherratt's for either lozenges or a powder. Witness first asked Mr. Ramsay, the assistant, for a powder. When he got home, he found his brother lying on the sofa, and his grandmother said he had better give the deceased the powder, and he did so, with about the third of a lozenge. In about a quarter of an hour after the deceased commenced "shivering," and a doctor who was called in administered some medicine.

Mr. A. Ramsay, assistant to Mr. Sherratt, said the last witness asked for a worm powder for a boy five years old. Witness mixed a powder containing a grain of calomel and a grain of santonin. In taking down the bottle containing the latter, he accidentally let it fall, and it broke into pieces. He picked up with a knife sufficient to mix with the calomel. The boy was also served with a pennyworth of worm lozenges. On Monday, Dr. Walker, who had attended the deceased, called at the shop and questioned witness respecting the composition of the powder sold for the child M'Guinness, who he said had died from all the symptoms of poisoning by strychnine. Witness heard nothing of any strychnine getting into the bottle of santonin. Dr. Walker said that the powder was bitter, but calomel and santonin were not bitter. Dr. Walker tasted the powder and found it bitter. Dr. Walker was afterwards ill. Witness, who also tasted the powder, took precautions against anything serious by taking some medicine.

Mr. W. Sherratt said that his assistant told him of Dr. Walker's visit to the shop. Witness called upon him and found him suffering from all the symptoms of poisoning by strychnine. Dr. Walker stated that he had tasted the contents of witness's santonin bottle, which must have contained poison. Dr. Laing and witness did all they could for the sufferer, and during the evening it was found that the symptoms of poisoning had disappeared. All the poisons in the shop were kept separate in a cupboard. Witness had looked at the contents of the santonin bottle and had found crystals which were not santonin. There were strychnine crystals in the santonin in the bottle produced, Witness could only suppose that the wholesale vender had by mistake supplied witness with strychnine instead of santonin.

Dr. Walker said the deceased, when he saw him, was suffering from poisoning by strychnine. He saw no indications of carelessness either on the part of Mr. Sherratt or his assistant.

The jury returned a verdict to the effect that the deceased had been accidentally poisoned by the powder, in which strychnine had been accidentally mixed.—*Manchester Courier.*

Suicide of a Chemist and Druggist.

An inquest was held at Maryport, on the 31st ult., touching the death of Mr. Isaac Elliot, aged 41 years, chemist and druggist.

A servant to the deceased deposed that on the previous evening he came home the worse for drink, and shortly afterwards was found on the floor, unable to speak. Her mistress at once sent her for a doctor.

Mr. James Little said that when he was fetched by last witness he found Mr. Elliot quite insensible; his eyes were fixed, the pupils dilated, and he was in a state of coma. He was just dying when Dr. Pearson arrived. Saw Dr. Pearson pick a bottle off the floor, which he produced. The stopper was out of the bottle. The bottle contained prussic acid diluted; it was four per cent. strength, and that was quite sufficient to destroy life. He believed it was one of deceased's own bottles taken out of his shop. Half a teaspoonful would destroy life in from two to ten minutes. Saw deceased on Tuesday morning at the Athenæum; he seemed then to be in a low, desponding way. He always had the appearance of a man who was in the habit of suffering from depression.

John Elliot said deceased was his brother. Last saw him alive about ten minutes past eleven o'clock on Tuesday night in Crosby Street. He was coming from his shop, and going in the direction of his own house. Asked where he had been that time of night, and he said he had been at the shop. Witness said, "It is rather late to be at the shop at this time of night." He replied, "Yes; I have been for a bottle," and showed it to him. It was about the size of the one produced. Did not ask him what he was going to do with the bottle. He asked witness to go home with him, and he replied, "No, it is far too late; it is time we were both in bed." Bade him good night and they parted.

The jury immediately returned a verdict of "Died from taking prussic acid while suffering from temporary insanity."—*Carlisle Journal.*

Review.

Proceedings of the American Pharmaceutical Association at the Twenty-Fourth Annual Meeting, held in Philadelphia, Pa., September, 1876. Also the Constitution, By-laws, and Roll of Members. Philadelphia: Sherman and Co., 1877.

The arrival of the American 'Proceedings' before the issue of the British 'Year-Book,' the meetings of the two Societies having been held in the same month, is certainly a feather in the cap of the Transatlantic Association, although the delay in this country is due to so unavoidable a cause as the regretted indisposition of the editor. In any case, however, the issue so promptly of this volume, containing upwards of 900 pages, rather larger and about half of them printed in smaller type than those of the 'Year Book,' would be creditable to the proverbial smartness of our American brethren. In the amount of matter it contains it is stated to be the largest volume yet published by the Association.

An engraved portrait of the late Mr. John Milhau, a former president of the Association, adorns the volume as a frontispiece, and there are also three fairly executed lithographic plates, representing the *Rheum officinale*, *Eriodictyon Californicum*, and a group of vesicating insects, besides several wood engravings inserted in the text. The book may be described as being divided into two portions, the first half consisting of a series of reports presented to the Association at its meeting at Philadelphia, and the other mainly of the papers then read and the subsequent discussions. Thus there is the report of the Committee on the Drug Market, including a sketch of a proposed modification of the tariff, which, by the way, would still leave tartaric acid, for instance, chargeable with a duty of 15 per cent., calomel with 30 per cent. of its value, sponges with 20 per cent., cod-liver oil 20 per cent., gallic and tannic acids one dollar per lb., santonin three dolars per lb., salts of strychnia one dollar per ounce, etc. There are also reports of a Committee on Adulterations and Sophistications, one on Metric Weights and Measures, and another on the Legislation of the year. The report of the Executive Committee includes obituary notices of members deceased during the year.

But the most important and lengthy report is that by Mr. C. Lewis Diehl, upon the Progress of Pharmacy from July 1, 1865, to June 30, 1876. This report, corresponding to the first part of the British 'Year-Book,' extends over 368 pages, and contains an immense number of abstracts, many of them, we are glad to note, culled from our own pages. Although these abstracts are almost invariably condensed, they appear to represent well the gist of the originals, whilst the space thus gained allows the report to cover a very wide ground. They are grouped under the main divisions of Pharmacy, including Apparatus and Preparations; Materia Medica, including (*a*) Vegetable and (*b*) Animal Drugs, classed under their natural orders; Inorganic Chemistry and Organic Chemistry.

The report on the progress of pharmacy is preceded by an introductory chapter, which in our opinion is hardly so successful. It appears to aim at making a reference to almost all the subjects of the report; hence in some places approximating to a catalogue, and introducing a bewildering multitude of materials beyond the power of the reporter to disentangle. For instance, after the separation of cotoin from coto bark by Jobst has been mentioned on p. 33 it is again referred to on p. 49; a similar remark may be made as to the principles of dita bark, and also as to Tiemann's researches on vanillin; whilst Buchheim's and Dragendorff's researches on ergot are separated from Tanret's by several pages, including the section on inorganic chemistry. It is also rather late in the day to quote in such a summary, without any qualification, Dr. Peckholt's belief that the *Serronia Jaborandi* Guill., is "*the* true Jaborandi;" nor did we expect to find this plant classed under Rutaceæ in the report, as it belongs to the Piper family. We note an interesting remark of the editor upon the statement of Mr. Jackson that American ginseng (*Panax quinquefolium*) is always rejected, to the effect that its price rules high in the Southern and Western States, and that this is doubtless due to demand for export to China. But might it not also be due partly to a consumption by the Chinese immigrants in the States themselves? Mr. Diehl also contributes a useful list of about a hundred and fifty books and pamphlets on pharmacy and the collateral sciences, published in Europe and America during the year, which must have cost him considerable trouble to compile.

The papers read at the Philadelphia meeting were valuable and interesting, and occupy a considerable space in the volume; some of these we shall take the opportunity of reproducing. Last, but not least, there is an appendix consisting of a report of a committee on the Centennial Exhibition. We cannot congratulate the committee, however, on clearness of arrangement; for instance, bitter barks from Cape Colony, castor oil seed from British Guiana, and arrowroot from Bermuda, all occur under the heading of Fungi from New Zealand. But this report contains much curious information, especially that referring to the Chinese, Turkish, and South American exhibits of materia medica. Some of this also we hope to be able to pick out and string together for a future number of this Journal. Meanwhile we content ourselves with merely quoting the statement that the manufacture of alkaloids by Messrs. Jobst of Stuttgart amounts to 33,000 lbs. annually. On the whole, this new volume of the 'Proceedings of the American Pharmaceutical Association,' is a valuable contribution to pharmaceutical literature.

BOOKS, PAMPHLETS, ETC., RECEIVED.

Questions and Answers on Materia Medica, Medicine, Midwifery, Pathology, and Forensic Medicine, for the Use of Students Preparing for Examination. By W. Douglas Hemming, M.R.C.S., etc. London: Baillière, Tindall and Cox. 1877. From the Publishers.

Osterferien in Ligurien. Von F. A. Fluckiger. From the Author.

Anthracen: its Constitution Properties, Manufacture, and Derivatives, including Artificial Alizarin, Anthrapurpurin, etc., with their Applications in Dyeing and Printing. By G. Auerbach. Translated and Edited from the Revised Manuscript of the Author, by William Crookes, F.R.S., etc. London: Longmans. 1877. From the Publishers.

The Combined Note Book and Lecture Notes for the Use of Chemical Students. By Thomas Eltoft, F.C.S., etc. London: Simpkins, Marshall and Co. 1876. From the Author.

Obituary.

JOHANN CHRISTIAN POGGENDORFF.

On the 25th of January, Dr. Johann Christian Poggendorff, the well-known Professor of Physics in the University of Berlin, died in that city. The deceased was born in Hamburg, on the 29th of December, 1796, and had therefore just completed his eightieth year. Like many other celebrities in the department of the exact sciences, Poggendorf began work in a pharmacy, which he entered at the age of sixteen, and where he continued eight years. Upon leaving the pharmacy he entered the University of Berlin, where he gave himself up exclusively to the study of chemistry and physics, and, whilst still a student, published his first paper, 'Physisch-chemische Untersuchungen zur nähern Kentniss des Magnetismus der Voltaischen Säule,' and this title gives the key-note to those of nearly 150 papers attributed to him in the Royal Society's catalogue. In 1824, he undertook the work of editing the *Annalen der Physik und Chemie*, of which he lived to receive the jubilee volume. In 1834, he became Professor-Extraordinary of Physics in the University of Berlin, a post that he held at the time of his death; he also received the degree of Ph.D. In 1839, he was elected a Member of the Berlin Royal Academy of Sciences, and in 1844 the degree of M.D. was bestowed upon him by the University of Konigsberg. Besides his original papers already referred to, and numerous translations that he made for the *Annalen*, he assisted Liebig in the preparation of the first volume of the '*Handwörterbuch der Chemie*,' and in 1863 issued his '*Biographisch-literarisches Handwörterbuch zur Geschichte der exacten Wissenschaften*,' a large volume containing biographies, and illustrating the writings of scientific men of all nations and times.

Notice has also been received of the death of the following:—

On the 26th of December, 1876, Mrs. Susan Durant Kelley, Chemist and Druggist, Saltash, Cornwall. Aged 61 years.

On the 8th of January, 1877, Mr. William Nowers, Chemist and Druggist, Green Street, Kent. Aged 61.

Notes and Queries.

[537]. DRY ROT.—I should feel indebted for any information respecting the prevention of dry-rot in the woodwork of dwelling houses.

MEMBER.

[538]. TOOTH STOPPING.—"MOLAR" would feel obliged for a recipe for a non-expensive metallic tooth stopping, that thoroughly hardens.

[539]. ESSENCE OF MUSK.—I should feel much obliged if any reader would furnish me, in the next issue of the Journal, with a formula for making Essence of Musk in which the empty pods are utilized.

D.

SYRUPUS MATICO ET CORT. GRANATI.—According to Perret (*L'Union Pharm.*), this syrup is one of the surest and most effective astringents against dysentery, cholera morbus, acute diarrhœa, etc. It is employed either pure or diluted with water.

Fol. Matico	partes	20
Cort. Granati	„	120
Aquæ bullient.	„	1,200
Sacchari	„	2,000

The matico and pomegranate are infused with the boiling water, and allowed to stand, well covered, for twelve hours. The infusion is then filtered, and the sugar dissolved therein. Dose, a tablespoonful to a wineglassful.

Correspondence.

CHEMISTS' TRADE ASSOCIATION

Sir,—I fear from remarks I have heard, that the correspondence, published in last week's Journal may give rise to a feeling in the minds of some persons that a spirit of antagonism exists on the part of the Secretary and Executive of this Association to the Pharmaceutical Society.

The correspondence of Mr. Haydon was misconstrued; an explanation was given in my address last evening, at Edinburgh, which, with your permission, will appear in next week's Journal.

The resolution passed at the last Council Meeting, I take to be quite satisfactory, and a sufficient reply.

It seems almost superfluous to reiterate that no feeling exists on the part of the executive of this Association but one, namely, that the Pharmaceutical Society and the Trade Association should help each other and act harmoniously together.

THOMAS BARCLAY.

Newcastle-upon-Tyne, Feb. 14, 1877.

MILK OF SULPHUR.

Sir,—I feel that chemists carrying on retail business with a desire to do so creditably and reputably have much to thank Dr. Redwood for, on account of the common sense manner in which he has treated the milk of sulphur question, and they ought thoroughly to appreciate the skill he has displayed both in the oral evidence he has given when required, and in the exhaustive letter published in the Journal of February 3. I should like you to repeat two sentences of his letter which require the careful consideration of the favoured chemists who are not called upon to retail small parcels of drugs and chemicals or supply the numerous wants of the poorer class of the British public. He says: "In a class of men differing so greatly as do chemists and druggists in the circumstances under which they are placed, and the nature of the duties they are called upon to perform, it is necessary for individuals among them to be careful how they judge and may be disposed to condemn those differently circumstanced from themselves. The qualifications required for conducting a druggist's business in some localities are very different from what they are in others."

Mr. Chipperfield, in his letter of 23rd January, says: "I deny emphatically that there is a great and continuous demand for the genuine old milk of sulphur, and assert most positively that the reverse is the case." An *ipse dixit* is not of much use in an argument, unless well supported by facts, and I put mine against his, and "emphatically declare that there is a great and continuous demand for the genuine old milk of sulphur," and support it by facts coming under my own observation and experience. I assert that I have tried to sell sulph. præcip. in lieu of lac sulphuris, and my customers have continuously brought it back to me because it was not so white as they had usually been supplied with, and they could not so easily mix it with water, milk, or treacle. If I wish to retain my customers, I must sell them lac sulphuris, and I concientiously believe I supply to them what they ask for, and what they wish to have, and in so doing I am not deceiving them nor pandering to the weak fancies of people, who are, as Mr. Chippendale euphoniously expresses it, "exceptionally benighted."

I keep, as I think every chemist should do, Sulph. præcip. B.P., in stock, to use or sell if required, and 1 lb. of this preparation in my business will last out 1 cwt. of the milk of sulphur; and if any physician should, through inadvertence, write lac sulph. in a prescription, I should presume that he intended "sulph. præcip.," and dispense it accordingly; but with the "benighted public" the rule would be different—in each case I should supply what was wanted.

In this week's Journal, in addition to Dr. Redwood's masterly letter, we have Mr. Symons' very sensible and gentlemanly rejoinder to Mr. Brown, and considering that it comes from a "benighted" place like Barnstaple, it will bear comparison with the bold self-asserting effusion from "enlightened" Southampton. Another correspondent also turns up in my friend Mr. George Meo, who says, "Depend upon it, the lawyers will make very short work of the appeal;" and from the context of his letter one may suppose he means that the Runcorn decision will be confirmed. Well, we all know the glorious uncertainty of the law, but while the matter is *sub judice*, we can only hope that common sense and law will both be on the same side, by which of course I mean *my* side of the question. I cannot see with Mr. Mee that coffee and chicory mixture and milk of sulphur run *pari passu* with each other. Coffee and chicory are two different products—one a berry, the other a root—and were usually sold as pure coffee though mixed, but milk of sulphur is sold for what it is, a manufactured chemical containing sulphur and sulphate of lime. Mr. Mee likes his coffee and chicory mixture, knowing what it is, and enjoys it; and my customer takes his milk of sulphur, and though he may not swallow it with the same gusto that Mr. Mee does his chicory-coffee, yet when he takes it for certain ailments to which he is subject, and finds himself benefited thereby, he is satisfied with what he has purchased.

London, Feb. 6, 1877. JAMES SLIPPER.

Sir,—Is lac sulphuris and sulphur præcipitatum the same? Yes. Because lac sulphuris was a pharmacopœial name in 1721, and the formula was sulphur, one part, quick lime or salts of tartar, three parts; boil with sufficient water to dissolve the sulphur, filter while hot and precipitate with dilute vitriol. Then comes the 1746 Pharmacopœia, which orders to be used sulphur and quick lime. Boil, filter, and precipitating with dilute vitriol as before. The name given with the formula is sulphur præcipitatum, and at the end of the book is this important item :—"We change the name from lac sulphuris to sulphur præcipitatum." I have had the Latin Pharmacopœias from the library, and can swear that this is a correct rendering of the words employed by the compilers. These are the points which make lac sulphuris and sulphur præcipitatum the same. The process yielding a contaminated product is identically the same in both Pharmacopœias.

In the 1746 Pharmacopœia the name is changed from lac sulphuris to sulphur præcipitatum. The 1721 process is optional, and with salt of tartar would give a tolerably pure sulphur, the quick lime would be identical with the 1746 process. Surely the friends of contaminated milk of sulphur will soon see the errors of their ways.

Now, Mr. Editor, you will remember we had this subject on the carpet at Birmingham, when our noble friend, Mr. Bird, made a long defence of his opinions. But judgment is not given on opinions generally of interested (pecuniarly) persons, doing drugs wholesale amongst small shopkeepers; judgment is given in accordance with facts. Usage is a plea—some say it has been customary, and, therefore, not right to stop the sale. We do not wish to stop the sale of contaminated milk of sulphur as such; but like the grocer with mustard and coffee: if he sells a mixture of mustard and farina, he must label it a condiment; so with chicory and coffee, he must put on a label to the effect that it is sold as a mixture of chicory and coffee. This applies equally to contaminated milk of sulphur. Now this is the point, if the contaminated be demanded by the purchaser, the retailer must label it, "Milk of sulphur, with a variable quantity of sulphate of lime;" or, "This is sold as a mixture of sulphur and sulphate of lime," which the purchaser will not object to if he really requires the contaminated lac sulphuris. I have just a nut for some of our friends to crack. Of course, no one would think of doubting in these times of enlightenment, that chemical processes are carried out with chemical skill, and upon such grounds I would ask whether one part of sulphur and three parts of quick lime, boiled together in sufficient water and filtered while hot, the solution of sulphur thus obtained would be constant in its proportions of sulphur and lime? If either were in excess would not the filter remove most? Then, on the addition of dilute vitriol, how are we to account for the discrepancy of 30 per cent. sulphate of lime in some samples, if they are all made according to the 1721 formula? I think there ought not to be such a difference if they are made in accordance with the 1721 directions. It has been stated that this contaminated lac sulphuris is a by-product, and manufactured at mineral naphtha works, and is obtained thus: Into the vessel from which ammonia has been drawn, a variable amount of sulphur is put in while the contents are hot (the contents of the vessel); first, lime, into which is put sulphate ammonia; when the ammonia has passed off there remains sulphate and excess of lime, which, on addition of sulphur, forms the contaminated lac sulphuris. When an apprentice I know we used to get this article from the same place we got mineral naphtha.

Having written the former portion of this letter more than a week ago, I am glad to resume it after reading the long letter from our worthy and esteemed friend, Dr. Redwood, about whom I would not say an unkind word, for I am sure he is held in the greatest esteem by most of us, and I have felt great reluctance to have to say I differ with our friend. I think if my letter be carefully read we shall not be wanting to find that Dr. Redwood has not touched the true legal point at issue. I would draw Professor Redwood's attention to the 1746 London Pharmacopœia, which he has only half quoted, as also yourself, Mr. Editor, although at Birmingham I drew your attention to the fact, and as the legal Pharmacopœias are in Latin, and copies in the library—if I make a wrong statement in effect, I ask you to put me right, my papers are stowed by, and I, not knowing where to look for them, have to quote from memory. In the Appendix to the 1746 P. L. we find in the list of changed names (old names) lac sulphur changed to (new names) sulphur præcipitatum.

This, if correct, for which I vouch, all legal difficulties are at once settled. Sulphur præcipitatum, synom. lac sulphuris. In selling contaminated lac sulphuris it must be labelled, "Milk of sulphur, with a variable quantity of sulphate of lime;" or, "This is sold as a mixture of milk of sulphur and sulphate of lime." The time has now come that articles must be called by their names, in order to the proper carrying out of the Adulteration Act.

Wicker Pharmacy, Sheffield, G. ELLINOR.

Sir,—Notwithstanding the lengthy communication of Professor Redwood, and the ingenious way in which he handles the question, I am still of opinion that "lac sulphuris" should not contain any admixture of calcium sulphate.

It would only be wasting time and occupying your valuable space were I to dilate more fully upon the subject at present, seeing we shall not have long to wait till the sessions, when the appeal case, so well known as the "Runcorn," will be heard.

Throughout the letter of Professor Redwood, no mention is made of 'Gray's Supplement,' where, in common with every work on materia medica that I have consulted, "lac sulphuris" is given as the synonym of precipitated sulphur. I think this is to be regretted, as Professor Redwood stands alone on this point—so far as authors are concerned; but I am happy to say he is still one of England's brightest ornaments, the difference nevertheless.

Why an article should be made simply to please the ignorant customers of a few chemists and druggists I am at a loss to know, seeing there is only a difference of three pence per pound between pure precipitated sulphur and the adulterated milk of sulphur. In the drug trade, as in every other, I should advocate purity in all articles as far as possible, and I do not see why milk of sulphur should be an exception.

Mr. Symons is a very funny opponent. I am glad, for his sake, his communication was "cut down and mollified," since my porcupine might have been as bristling as his own.

In discussion we should always attack men's views, and avoid offensive expressions.

I must, Mr. Editor, thank you for the impartial manner in which you have acted, and permit me also to say I feel under a debt of gratitude for the space allotted to my communications.

HY. BROWN, L.R.C.P., L.R.C.S., etc.

Northallerton.

Sir,—Upon reference to several old Pharmacopœias I find for many years there were only two kinds of sulphur used in medicine and pharmacy, the one, lac sulphuris, being generally prescribed for internal use, whilst for external use the flowers of sulphur (sublimat. sulph.) was ordered. At that time lac sulphuris was directed to be prepared with crude sulphur, quick lime, potass subcarbonate, and then precipitated with sulphuric acid (dilute), which not only precipitated the sulphur but also sulphate of lime. It continued to be made in this way for many years, and was looked upon by the faculty as the most reliable and useful preparation of sulphur. Subsequently the formula was altered on account of the great percentage of sulphate of lime, hydrochloric acid being ordered instead of sulphuric. Royle's 'Materia Medica' (1868) in describing "Sulphur præcipitatum—lac sulphuris or milk of sulphur" is very decisive in ordering its preparation with hydrochloric acid; it goes so far as to say "This preparation has been nearly out of use of late years on account of two thirds by weight of that sold in the shops having consisted of sulphate of lime" and it then goes still further, saying "Sulphuric acid may be fraudulently substituted for hydrochloric." The present Pharmacopœia does not mention the old milk of sulphur (prepared with sulphuric acid) at all, the presumption being that the compilers of that work looked upon sulphur præcipitatum as the true lac sulphuris, which without doubt is meant and has been recognized by men of eminence in the medical world as the only milk of sulphur. It may be argued that the milk of sulphur prepared with sulphuric acid is more beneficial in some cases. Perhaps so; we will take it for granted it is better for certain complaints; but why should we use it in all cases. Certainly the sulphate of lime is injurious in the majority of them. If sulphate of lime is such a good dilutant of sulphur, why should not doctors write a prescription, "Sulphur pure, 1 part, sulphate of lime, 2 parts?" Then the medical man, chemist and patient, would know what was meant. Surely if a customer asks a chemist for three ounces of milk of sulphur, the chemist is morally and legally bound to supply the milk of sulphur prepared according to the most approved authority, and not supply him with one ounce of sulphur, and two ounces calcium sulphate.

Some people may say, "But I like it better made the old way, it mixes more readily with water, it does this, and does that." My answer is, would a grocer who sold coffee with an amount of chicory mixed therewith be amenable to the Adulteration Act, if he could prove that chicory made it more agreeable to the taste, and made a much better infusion than it would without the admixture? If he was not, then the Adulteration Act would be a farce and a dead letter, for who could not find some one to endorse the most fanciful opinion as regards taste; and in conclusion I say so long as the present Adulteration Act preys upon tradesmen, it ought above all things to apply to drugs, on the purity of which at times so much is at stake.

W. P. B.

A New Form of Competition.

Sir,—I shall be obliged if you can spare me space to draw the attention of the trade to a growing habit amongst a certain class of wholesale houses of interposing between the retailer and his customer: I mean by their putting up ordinary simple medicines, such as syrups, pills, etc., and introducing these semi-proprietary medicaments directly, or indirectly, to the medical profession accompanied by notes, circulars, testimonials and other semi-quackish methods, stating that A.'s x-y cod liver oil, or B.'s pil. x+y+z or C.'s syrup x_4+y_2, and so on, is ever so much better than anybody else's; and further, in order to ensure the only pure and correct thing, these preparations must be designated by their respective hieroglyphics, whenever the prescriber may require such a preparation or drug.

It is no uncommon matter, nay, it has become almost a regular thing of late, to find prescription after prescription disfigured by such unprofessional characteristics.

Every dispenser must feel, if he has a spark of manly feeling in him, that it is a gross insult to his capacity and ability (to say nothing of the dishonesty indirectly often imputed to him on the printed labels, etc., that purchasers must be careful that the orthodox seal or label is on the package) to have a prescription left with him to dispense containing only ingredients that he is as fully able to compound accurately and with as pure materials as A., B. or C., but which he is instructed by the prescriber to obtain from these pushing men, at no small cost, inconvenience and perhaps delay. I cannot conceive a greater indirect censure upon the examinations of the Pharmaceutical Society than these proceedings carry with them. Surely men who have passed their examinations (and they are now sown broadcast over the country) ought to be considered equal to all ordinary emergencies, ought to be able to compound simple remedies, ought to be able to discriminate between pure and worthless drugs and chemicals; but if not, and if these specialists are needed, what a comment upon the results of our examinations

The remedy for this unhealthy state of things, for such an innovation on the just rights of the dispenser and retailer is unhealthy, is fortunately in the hands of the latter; they very nearly always have the ear of neighbouring prescribers, and if they will only make good and judicious use of the opportunities open to them, and if a determined face were set against this modern practice, which can but degrade the pharmacist in the eyes of the medical profession, the evil would soon be stamped out; the wholesale men, A., B. or C., would speedily find their best interests in directing their enterprise towards their best friends—the retailers—by offering their goods in the usual way of trading, and not interfering between the retailer and his customer, — an occupation foreign to a wholesale transaction,—whilst the minor makers of simple specialities would speedily be atrophied off the stage.

If after so many years of downright hard honest work, and if after so large an expenditure of money the Pharmaceutical Society has not succeeded in creating a class of men thoroughly able to accomplish all the work required by the medical profession, without having perpetually to fall back upon special makers of simple remedies, it is quite clear there must have been a tremendous miscarriage of effort. But, sir, I am bound to say, and to say it distinctly, that no such miscarriage has occurred, that hundreds of men, aye, and the great majority of men now practising pharmacy, are well able to do all that can possibly be required of them, and there is consequently not the smallest need for a class a specialists, whose avocation if once fairly established must necessarily result in the degradation of our class, and deprive the intelligent, qualified and competent man of his legitimate position and emoluments.

I am far from discouraging legitimate enterprise, but the operations above alluded to are, in my opinion, neither legitimate nor necessary.

In re, e re.

Nux Vomica Bark.

Sir,—A good deal of interest having been shown at the evening meeting, on Wednesday last, as to the nature of the alkaloid or alkaloids present in nux vomica bark, I shall be glad if you will allow me to state that, having, a short time since, through the kindness of Messrs. P. Squire and Son, acquired a supply of this now rather rare bark, I hope before long to be able to give some definite information on the subject, which has for some time past been of considerable interest to me.

Taunton, Feb. 11, 1877. W. A. Shenstone.

A Gum Query.

Sir,—About eighteen months ago I wrote you, and sent a sample of a white gum arabic which yielded an extraordinarily viscid mucilage. You replied that you had tried the sample and found nothing amiss with it, so I concluded the fault to have arisen from the presence of a small quantity of a gum allied to tragacanth, which occurred only in certain portions of the bulk, and that which I sent you was free from it.

In the *Pharmaceutical Journal*, of July 29, 1876, a correspondent, under "Notes and Queries," notices the same thing, and puts the question, "Has anyone noticed a sample of gum which makes a mucilage more like white of egg?" but no one replied.

A lozenge manufacturer some time since offered a sample of good Turkey gum (of which I enclose a portion) remarkably free from brown pieces, at a low price, because they were over stocked (8*d* per lb.). This I find is precisely similar to that which I wrote you about before. Thinking it might be caused by the presence of a small quantity of an ally of tragacanth, I picked out from the bulk 2 drs. of those pieces which were quite transparent, or exhibited any abnormal appearance, and labelled it "False Acacia;" also I picked out 2 drs. of the most genuine looking, "opaque from numerous minute cracks," and readily crumbling between the fingers, and labelled it "True Acacia." To each of these samples 3 drs. of water were added and stirred repeatedly. This experiment proved that both gums were identical. Both appear to dissolve completely (hence not bassorin or cerasin), but the "False" showed the characteristic viscidity first; in neither does it appear until after from eight to twelve hours, and still continues to develop till twenty-four or thirty-six hours, although apparently it had previously completely dissolved. So tenacious was the mucilage that on attempting to lift the stirring rod out, the whole might be raised (pot included), and would only slowly fall! It agrees with the B. P. "characters and tests;" the "Adulterations and Substitutions" of Pereira's Materia Medica, would not detect it, and yet it is quite distinct from the ordinary kind. Commercial travellers and wholesale houses know nothing about it. It certainly deserves investigation, and I should be glad to receive information on the subject.

75, *High Street, Barnstaple.* R. H. PARKER.

"APPEAL TO THE BENEVOLENT."

Sir,—Will you allow me again to announce the additional subscriptions that have been received since my last communication of the 27th ult., in response to my appeal which appeared in the *Pharmaceutical Journal* of the 13th ult.?

WATER FLEAS.

Sir,—Allow me to supplement Mr. Macadam's interesting paper on the Water Flea (*Daphnia Pulex*), printed in the Journal of the 3rd inst., by a few remarks on its interest as a microscopic object. Both the *Daphnia* and its congener, the *Cyclops quadricornis*, abound in every clear pond or pool in this part of the country during the warmer months, and a bottle of water taken from either, at the proper time, will doubtless contain many, which may be readily seen by the unaided eye. The daphne may be known by its somewhat circular form and the steadiness of its movements. The cyclops by its parsnip or pear-shaped body, and the rapidity with which, by sudden jerks, it propels itself through the water.

If one of the former be taken up by a dipping tube and the tube held vertically for a few seconds, the daphne will sink to the bottom of the fluid and may then, with the drop of water containing it, be readily deposited on the bottom of the animalcule cage. The cover should then be cautiously put on so as to fix without crushing the little crustacean. A most interesting and instructive object is then at hand.

The paddling of the gills (both feet and lungs to this creature) causes a constant current of water to flow past and aerate the body, bringing also a never ending supply of food to the mouth; any tit-bit being caught and swallowed, all else abruptly rejected. The extreme transparency of the carapace, and in fact of the whole body, enables us distinctly to see the various physiological operations, which, on a larger and more complex scale, are carried on within ourselves. The pulsation of the rudimentary heart; the circulation of the nutritive fluid (or blood) over the body generally, and through the antennæ; the deglutition of the food and its active digestion in the œsophagus (with some of the rotiferæ or wheel animalcules, infinitely smaller than our daphne, the food is pounded and crushed by two mighty bones placed like anvil and hammer in the gizzard); the passage of the food along the alimentary canal, and the excretion of the fæcal matter. This and much more in a creature for which the head of a pin would afford good standing ground. Possibly also in others one thousandth or one ten thousandth part the size, for our daphne is truly a giant among the diminutive host. Its one eye or cluster of ocelli turns as it were on a pivot, and the movements of the muscles effecting this may be watched with interest.

To our astonishment we are also admitted to the sight of generations yet unborn, for within the eggs, contained on back, under the shell, of the female, the spasmodic attempts of the pre-infantile daphne to stretch its limbs are, to say the least, amusing to witness.

33, *Norfolk Terrace, W.*, A. P. BAKER.

"*Kino.*"—*Hashish* is the Arabian name given to the dried tops of the *Cannabis Indica*, gathered some time before the seeds come to maturity. See *Pharm. Journ.* [3], vol. iv., p. 696. It is used for smoking, and is also made up with flour and other substances into a kind of sweetmeat.

"*Starke.*"—A person who has only passed the Assistant's examination at Apothecaries' Hall cannot legally "keep an open shop for the retailing, dispensing or compounding poisons," or "take, use or exhibit the name or title of chemist and druggist, or chemist, or druggist." The registration clauses of the Pharmacy Act do not apply to the business of wholesale dealers in supplying poisons in the ordinary course of wholesale dealing.

C. Chorley.—"Wild cherry bark, bruised, two ounces; proof spirit, twenty ounces: digest for fourteen days, express and filter; or the tincture may be better prepared by displacement or percolation.

"*Extract.*"—See *Pharm. Journ.* [3], vol. i., p. 863; vol. iii., p. 104.

"*Rheum.*"—See *Pharm. Journ.* [3], vol. iii., p. 212.

"*Alpha.*"—See vol. vi., p. 921, and the present vol., p. 289.

B. Clifford.—Ganot's 'Physics' (Longmans); Deschanel's 'Natural Philosophy' (Blackie).

"*Alpha.*"—We should recommend you to test the strength of the solution or get some person to do it for you.

W. H. S.—See the note on p. 676.

F. L. P.—There is no such name on the Register of Chemists and Druggists.

"*Pharmaceutical Student*" is referred to the rule respecting anonymous communications.

"*Quære.*"—No.

"*Apprentice.*"—See Wanklyn's 'Milk Analysis," published by Trubner and Co.

"*Gelosa.*"—Obviously no person who is not a Member is entitled to represent himself as such. We have consulted the Calendar and do not find your name in the list of Members.

T. L. Edden.—(1 and 3) *Fumaria hygrometrica*; (2) *Tortula intermedia*; (4) Either *Weissia microstoma* or *viridula*: it is impossible to say with certainty until the capsule is mature. (5) *Tortula muralis.*

W. B. Jevons.—Apply to the Secretary of the Apothecaries' Company.

"*Inquirer.*"—Squire's formula for cold cream is as follows: white wax, 1; spermaceti, 1; oil of almonds, 6; rose water, 9; otto of rose to perfume it. Melt together, by means of a water-bath, the oil, spermaceti and wax, then gradually add the rose water and stir till cold.

"*A Dispenser.*"—The B. P. acid should be used.

"*An Old M.P.S.*"—If possible, consult the prescriber.

R. H. M. (Sunderland).—Only the Commissioners of Inland Revenue can give a decisive answer to your question.

"*Pinus.*"—(1) We cannot say. (2) No.

"*Geiger.*"—We should think not.

T. Stokoe.—The best plan is only to keep such stock in proportion to the demand for it as will allow of its frequent renewal.

W. T. H.—(1) Church's 'Laboratory Guide for Agricultural Students' (Van Voorst). (2) No.

Errata.—In Mr. Yewdall's letter on p. 648, col. 1, line 29, for "having" read "have." In the following letter the sentence with respect to the hours of Sunday trading in Glasgow should stand, "The Sunday hours in the better class establishments are from 9 a.m. to 7 p.m., closed during the hours of church service."

COMMUNICATIONS, LETTERS, etc., have been received from Mr. Pitman, Mr. Wilkinson, Dr. Lindsay, Brummagem, Chemist, H. H. S., J. B.

"THE MONTH."

The medicinal plants in blossom this month are exceedingly few in number. Although the hedges in the country are looking all the brighter for the drooping yellow catkins of the hazel and the purple tinted ones of the alder, and although snowdrops, periwinkles and primroses are peeping out here and there, with an occasional sprinkling of the golden blossoms of the lesser celandine, yet there are at present only two wild plants in flower which we can claim for medical botany; these are the elm and the sweet violet.

The blossoms of the *Ulmus campestris*, L., are usually developed most freely on the topmost branches, and it is only rarely that they are found within reach of the hand. On this account the little bud-like tufts of flowers are often mistaken for opening leaf-buds. If one of these tufts be pulled off, it will be found to consist of about twenty-six small flowers, each one with a scaly bract at its base, the whole number being supported on a very short general peduncle, so that the inflorescence has upon close inspection the appearance of a small umbel. The flowers however do not, as in the true umbel, open centripetally, but irregularly, as if the inflorescence were a condensed umbellate cyme. Each little flower consists of a pale green funnel-shaped calyx, divided above the middle into five parts, which are tinged towards the tips of a pinkish purple colour, and are fringed, as well as the bracts, with a row of delicate unicellular hairs. The five stamens are twice as long as the calyx, and consequently protrude beyond it. The anthers, at first pinkish, become soon afterwards of a dark purple colour. The ovary is crowned with a bifid stigma, and ultimately forms the curious almost circular, pale, winged fruit (samara) which a month or two later strews the lanes and covers the ground with what at first sight looks like a shower of broad deciduous bracts.

The violet (*Viola odorata*, L.) is such a common flower that it does not generally receive the attention from the young botanist which its peculiarities deserve. The young leaves afford an instance of involute vernation, and the base of the plant presents creeping stems which illustrate the stolon. The calyx consists of five spurred sepals, and the corolla of five unequal petals, only the lower one of which is spurred. The five sessile anthers have each a brown membranous appendage at their apex, and two of them have spurs which project into the spurred petal. The stigma is beaked. The appendages of the anther have a curious purpose. As the flower hangs down they are closely applied to the style, forming a sort of bag in which the pollen is confined and prevented from falling on the stigma of the flower. An interesting account of the object of this singular arrangement will be found in Sir John Lubbock's 'British Wild Flowers in Relation to Insects,' p. 61. In May and June the violet produces flowers very different in appearance from those now to be seen; they are small, closed and almost apetalous, but nevertheless produce seed freely. On the flower stalk of the violet may be seen two minute bracts, which might be easily overlooked by a casual observer, yet these bracts afford a means of distinguishing one species from another; thus there is another species of violet in blossom this month which is quite odourless (*Viola hirta*, L.), in which these bracts are situated below the middle of the flower-stalk, while in the sweet scented violet they are above the middle. The latter differs also from the hairy violet in having downward hairs on its leaf-stalks, while the hairy violet has spreading hairs. It is commonly reported that more syrupus violæ is made from pansy flowers than from violets. Besides the larger size of the flower of the pansy it differs from the violet in having a hollow rounded stigma.

At Kew the only plants in blossom in the economic house are the *Drimys Winteri*, which is still blooming most luxuriantly, and the kola nut plant with its small green unisexual flowers. In the winter garden, however, there may be seen a small buchu plant (*Barosma crenulata*, Hook.) in flower. In habit this plant closely resembles the pretty *Eriostemon*, whose white starlike blossoms form so pretty an ornament to greenhouses at this season of the year. A figure of the plant is given in part iii. of Bentley and Trimen's 'Medicinal Plants;' the leaves in the Kew plant are not erect as represented in that drawing, but spreading or even slightly recurved. The structure of the flower is rather curious. In size and in general appearance it slightly resembles that of the stitchwort (*Stellaria Holostea*, L.). The five stamens are alternate with the petals and at first spread horizontally on a level with them. One by one the stamens become erect and after shedding their pollen bend backwards and become recurved between the petals and below their level. During this process the filaments elongate so that the young stamens may be known by their shorter filaments. Alternately with these five perfect stamens are five abortive filaments (staminodes), which, being exactly underneath the five projections of the carpels, appear to belong to them, and it is only when they are depressed with the point of a pin that they are seen to be distinct and to arise from beneath the carpels.

In the Cactus house, a specimen of *Aloe plicatilis*, Mill., may be seen in blossom. This is one of the species from which an inferior kind of aloes is made in South Africa. The flowers are of the usual tubular type found in most aloes, but are rather paler in colour than in several other species, and the spike consists of but few flowers. The blossoms are about 1½ inch long, and are of an orange yellow tint. The stem is repeatedly branched in a forked manner, and has a corky cracked surface. The branches terminate in a dense tuft of succulent leaves arranged in two opposite rows. The leaves are obtuse, convex, below, from 8-12 inches long by about 1 inch broad, shaped somewhat like a paper knife, and slightly curved upwards, those in the centre of the tuft being longest, so that each tuft looks like a slice taken out of the centre of a large onion. It will thus be understood that the appearance of the plant differs much from that of *Aloe ferox*, Lam., and *A. arborescens*, DC., in which the tapering leaves form rounded tufts like the common yucca. There may also be seen in blossom now the *Plumbago rosea*, L., the roots of which are used in India as a vesicant. Its long spikes of rose pink salver-shaped flowers, with the calyx covered with short glandular hairs, enables it to be easily recognized.

In the grounds, the periwinkle (*Vinca minor*, L.) may be seen in blossom in shady places; this plant as well as the larger species (*V. major*, L.) was used in Gerarde's time as a hæmostatic, and has lately been brought into notice again for the same purpose. The curious stigma in the flower is worthy of observation; the style readily separates from the apex of the ovary, and then exactly resembles in shape one of the round brushes used for blackleading fire grates. This appearance is due to a shortly stalked tuft of hairs placed in the centre of the circular stigma.

Here and there throughout the grounds may be seen also the yellow funnel-shaped flowers of *Forsythia suspensa,* an oleaceous plant, the capsules of which are used by the Chinese as an alterative and emmenagogue. The roots are said to be slightly poisonous and to possess antifebrile properties.

The Botanical Gardens at Regent's Park present at present nothing worthy of special remark; the mezereon and star anise plants still remain in full blossom, and the almond (*Amygdalus communis*, L.) is just opening its flowers. At Kew the latter is already in full blossom.

The almond tree is one of the prettiest objects in the suburban streets of London in the early spring, when its leafless branches are covered with delicate pink flowers. The blossom presents no remarkable features. The petals are very fugacious, falling soon after the flowers are gathered. The stamens are about thirty in number, and are attached to the tube of the calyx; the flower-stalks are surrounded with scaly bracts. The flowers of the bitter almond are more rarely seen in London. Its flowers are larger than those of the sweet variety and of a white colour, the base of the petals only being pink. It was most probably this variety to which the poet Moore alluded when he spoke of—

"The silvery almond flower
That blooms on a leafless bough."

Although the almond flowers profusely, its fruits are only sparingly developed in this country. A few produced last year may, however, still be seen on some of the almond trees at Kew.

The Cornelian cherry (*Cornus mascula*, L.) is now just coming into bloom in the Regent's Park Gardens. The flowers, which are small, greenish yellow, and, like most plants of the Cornaceæ, four-parted, are arranged in small umbels proceeding from the joints where the leaves of the last year have fallen off. The ovary is inferior, and the style surrounded by a small cup-shaped disk. The flowers are used by the Turks in diarrhœa, and from the acidulous astringent fruits, which are of a cornelian colour and about the size of an olive, a decoction is made which is employed for a similar purpose. From the wood the Turks are said to obtain the dye for their red fez.

In the drug market during the last month *Xanthium spinosum* has made its appearance, a drug which it will be remembered has been recommended as a preventive of hydrophobia. We noticed in one of the daily papers a few days ago, that several people had been bitten by a mad dog, and had been taken to the London Hospital. There is therefore an opportunity for its value, if any, to be tested.

Coca leaves, jaborandi, and boldo still figure at the sales. We have also noticed copalchi bark (*Croton niveus*, Jacq.), which has appeared under the name of white bark. It bears some resemblance to cusparia bark, and has indeed been sold for it on former occasions when it appeared in this country. From that bark it differs in exhibiting, where denuded of its white soft outer coat, an appearance of having been rasped. Under a lens this is seen to be owing to a number of minute oblong pits which cover its surface. It is remarkable for containing an alkaloid which gives the same reaction as quinine with chlorine and ammonia. It does not, however, form a compound similar to herapathite with iodine. Another bark, offered under the name of black bark, appears to be that of some species of *Exostemma.* It is rather thin, flattened, and very hard. With the aid of a lens its transverse fracture appears resinous and stratified.

Under the name of genocardium oil we have seen a white fatty substance, imported from Bombay, which seems to be the oil obtained from the seeds of *Gynocardia odorata*, R. Br. In India it is known as Chaulmugra oil and forms one of the most valued native remedies in leprosy and skin diseases; it is official in the Indian Pharmacopœia as an alterative tonic, and is certainly worthy of trial in this country.

A sample of remarkably fine sagapenum has been shown to us by Messrs. Hearon, Squire and Francis, which is almost unique. It occurs in the form of distinct tears varying in size from a pea to a hazel nut. Some of the tears have seeds and fragments of umbels attached to them; this seems to indicate that these tears must have been produced on the flowering portion of the plant. The drug was imported from Bombay, and we believe only one case was in the market. Neither Hanbury nor Pereira notice a variety of this kind, but some similar tears are in the Museum of the Pharmaceutical Society; they were presented by Messrs. Corbyn and Co., and are believed to be about 150 years old. About six cases of spurious buchu (*Empleurum serrulatum*, Ait.) have lately been offered for sale in London. These leaves may be distinguished from the narrow-leaved buchu (*Barosma serratifolia*, Wild.), which they much resemble in shape, by their having the tip of the leaf sharply pointed, where as in the buchu it is blunt and has an oil gland exactly in the apex. The buchu leaf is figured in Bentley and Trimen's 'Medicinal Plants,' part vi. The taste and odour of the leaves are different from those of true buchu. Bellerica myrobalans, the fruit of *Terminalia bellerica*, Roxb., has been offered at Exeter for sale as galls. This is rather a dangerous substitute, since these fruits have been known to produce symptoms of narcotic poisoning. They may readily be distinguished from galls by sawing them open, when they are seen to be fruits and to contain seeds instead of insects; externally, also, they taper at one end. From Cork we have a specimen of Asarabacca leaves and flowers, supplied instead of *Chimaphila umbellata*, Nutt., whether by accident or ignorance it is impossible to say. A case of Nepaul aconite root (*Aconitum ferox*, Wall.) lately opened proved to contain a large quantity of the dried dung of some animal, which was probably used in drying the root, and afterwards packed in to make up deficiency of root, since it only occurred in one case out of several.

These instances show that it behoves both the wholesale and retail druggist to thoroughly examine all their goods. The arrival of aconite root from Japan, as noticed at the last evening meeting, may be welcomed as a herald of competition. The aconite root which at present comes into this country is disgracefully bad, and is usually composed in large quantity of old and comparatively worthless roots, with a large proportion of stem attached to them, and is also occasionally adulterated with other roots. The Japanese article is clean, of good quality, and should the examination of its active principle prove it to be as active as the European aconite, it will insure its good sale, and cause it to replace the very inferior drug at present supplied from the continent.

Professor Xavier Landerer, of Athens, has found that oil of *Satureia Thymbra*, Sibth. (?) is a prompt remedy against toothache, applied either as oil or by chewing the leaves of the plant. It is curious to remember this in conjunction with the fact that carbolic acid, oil of cloves, and a number of benzene derivatives act in the same way, for it would appear to indicate in common with other observations that physiological action is related in some very definite way to the chemical constitution of bodies.

Since our last monthly article, Dr. Burdon Sanderson's paper on "Contagium Vivum" has made its appearance, but there is little in it that is at all new to science. He reviews the various theories relative to disease, and says that "contagium vivum" derives its power of producing disease by reason of the life which enters into its nature, and which has been derived from the living body. He views all infectious material as derived from infected bodies, and argues that no fortuitous agglomeration of atoms could produce "contagium vivum." This "vivum" is compared to ferments which produce change while remaining themselves unchanged, and it is pointed out that contact, in the ordinary sense, is not necessary for contagion; it is enough that there should be a simple transfer of substance from one body to another.

The points of similarity of Dr. Sanderson's theory with that held by Liebig are at once evident; but Liebig had, we think, a better appreciation of the nature of "contagium vivum." He did not place it outside the list of ordinary substances; it was enough for him to know it was subject to the same laws as all other substances. In the present day medical men are as a body, owing to their non-acquaintance with chemical science, considerably behindhand in some respects: the sooner they abandon extravagant hypotheses regarding vital force and are content to accept matter and force as the two factors of all things, the sooner we shall advance in our knowledge of disease and our power to prevent contagion. While speaking of this matter we may mention that on February 8, Mr. Kingzett delivered a lecture before the Society of Arts, in which he described the antiseptic and other properties of the solution obtained by the atmospheric oxidation of turpentine in the presence of water.

Water is a subject which at all times commands considerable attention, and during the past month it has received even more than usual, and this in various directions.

At a meeting of the Physical Society of London, on January 20th, Professor Guthrie read a paper on the state in which water exists in jellies, and exhibited a number of india-rubber balloons filled with water, to illustrate the nature of jellies. When a jelly sets, he said, "it is assumed that the solid matters collect in the form of cells containing liquid, which burst on the application of heat." By weighing at intervals one of the india-rubber bags (as exhibited) he has determined that evaporation takes place from its surface; thus, one which weighed initially 749·4 grms., in the course of twenty-four hours lost 0·95 grm.

This subject is of extreme interest from the contrast presented by such water to that of crystallization. Chemically speaking, there appears to be no difference between the state in which water exists in crystals and in colloids, except that these represent the extremes of a series. In both cases the water is in combination, not merely associated with the material forming the body of the crystal or the colloid, as it exists, say, in cold flour paste. If this paste, however, be boiled, then the water combines with the substance, and the mass sets more or less on cooling. A good instance of the colloidal stat of water is presented, for example, by the brain and other animal tissues. This presents a solid mass, from which not a drop of water can be squeezed out, and yet it contains more than 80 per cent. of water which is in a state of combination with the principles that enter into the constitution of the brain. The fact that Professor Guthrie's balloons lost water by evaporation from their surfaces does not prove that the water was not previously in combination with the other substances. Crystalline substances often present similar experiences; indeed, Professor Church and others have shown that many definitely crystalline substances give off water in mathematical amount, under various conditions of temperature and pressure. Thus in some cases crystals lose water *in vacuo* and will lose a further definite quantity on exposure to a temperature of 100° C. Some again, lose a definite amount on mere exposure to the air, and this, again, differs at times from that quantity which is lost by drying over sulphuric acid.

What then is the difference between the states of water of crystallization and water of colloidation? The only difference appears to us to be of the nature of degree rather than of kind. One may imagine that a substance which has the power to arrange itself from a state of fusion or solution into one where the material exists in a glometrical form around certain axes, is capable of combination with water only in definite proportions, and it may be, even, that the water lost by such crystals *in vacuo* is referable to a certain axis, and one distinct from that which furnishes the water dispelled by a temperature of 100° C. Such crystalline substances have low atomic weights compared to colloid bodies, as a rule. Colloid molecules have weights ranging up to hundreds and thousands compared with hydrogen as unity, and such bodies are rarely, if ever, crystalline. It is such substances which seem to have the power of combining with an almost indefinite proportion of water. Starch and the forms of albumen are examples of such bodies, and at least there can be no doubt that the large amount of water associated with various states of these substances is as distinctly in chemical combination as the water of crystallization of sodic sulphate. The nature of the combination is, it must be admitted, little understood; the same however is to be said of water of crystallization.

The subject of water analysis has lately received some attention from Mr. M. F. Anderson, L.R.C.P., who, writing to the *Sanitary Record*, disputes the correctness of the results obtained by Wanklyn's ammonia process. His experience is that the dangerous elements of bad water do not yield ammonia by Wanklyn's process, but nitro-oxides. That is to say, in the distillation process, employing permanganate of potash, some nitrogen is often oxidized and remains behind, instead of passing over as ammonia. He arrived at these conclusions by estimating the organic nitrogen by Wanklyn's method. This done, he finds that if the residue from this last operation be submitted to the process for estimating nitrates and nitrites, such an amount is found present that the difference between it and the true figure for these bodies represents the nitrogen oxidized by the permanganate of potash. To this startling statement Mr. Wanklyn speedily replied to the effect that Mr. Anderson's results were incompatible with the researches published in 1868 by him (Mr. Wanklyn) and his colleagues. As for the so-called source of error, he explains it as a mistake on the part of Mr. Anderson, who has obtained his results not unlikely by employing permanganate of potash containing much nitrates. As nitre is employed in making permanganate of potash, Mr. Wanklyn's explanation is probably the correct one, bnt at the same time the point is undoubtedly worthy of absolute corroboration one way or the other.

To one statement of Mr. Anderson we must certainly take exception. He states that it is hard to conceive albumen to be of so dangerous a character when present in waters as is ordinarily supposed, and further states that gelatin is not albumen, although in Wanklyn's process it is determined as such. True it is, and rightly so. Gelatin is one of the forms of albumen and no substance more readily undergoes processes of decay and putrefaction, and therefore while to such processes we refer the sources disease, we must consider the presence of these substances in drinking water as decidedly dangerous.

Mr. Wanklyn has himself overstepped, in our opinion, the safe limit of inferences to be drawn from the analysis of waters, and this in rather an unfair manner. In a paper which he read at the Glasgow meeting of the British Association on the influences of the mineral substances present in drinking waters on the health of the community, he attacked the Taunus water, on the score that it contains nearly 100 grains of calcic carbonate and 200 grains of sodic chloride per gallon. London drinking water contains only from 13 to 20 grains of carbonate of calcium per gallon. The author of the paper said that until we had more knowledge regarding the influences of the mineral substances contained in waters on the health of those consuming them, we should avoid as far as possible waters which depart in composition from those ordinarily accepted as standards. Nevertheless he did not adduce a single fact to show that such mineral substances are injurious. On the other hand, as Dr. Carr pointed out, they are often highly beneficial, and it is remarkable that the Kentish children are almost universally possessed of straight limbs and good bones, a state of things most probably referable to the hard water consumed in Kent.

A man would not consume ordinarily more than one or two bottles of Taunus water per day, and hence the quantity of carbonate of calcium thus introduced into the system is practically but little, and even that, we are disposed to think, becomes calcic chloride in the stomach and is chiefly eliminated in the same state in the urine. If any be assimilated it is an useful food, we contend, even for fully grown men, whilst as for salt our daily dinner experience proves its value as a food. Those who prefer Apollinaris water may take it, but others will probably continue to consume Taunus water in spite of the soap-bubble which Mr. Wanklyn has blown with it.

Speaking of sensations, we are reminded of one which has been recently got up about condensed milk, the chief facts of which we give here. Dr. G. Griffiths, in a letter to the *Daily Telegraph* (January 24), called attention to what he termed the extremely deleterious nature of condensed milk, which, according to him, ruins the health of infants fed upon it, and is competent, he goes on to say, to produce diarrhœa and a sort of diabetes. Of course this letter has elicited some discussion in the medical world, and Dr. Griffiths has been unanimously "sat upon." Many of the medical men who have replied to his letter state that they have actually prescribed condensed milk in cases of diarrhœa, and have never even heard of diabetes as resulting from its use. It is scarcely necessary to add that the whole thing was an instance of the kind of sensational humbug too often experienced in the medical world.

A curious case of lead poisoning has been recorded by Dr. de Loos, in the *Weekblad van het Nederlandsch*, etc. It was brought about by the consumption of vegetables that had been grown on a piece of land where twelve years previously had stood a white lead factory. Some of the vegetables yielded lead on incineration, a statement of more than ordinary interest, since it raises the question whether the lead was in chemical combination with the principles entering into the constitution of the vegetable tissue —a combination similar to that in which copper is known to exist in the body and in the colouring matter of the feathers of the plantain-eater.

In a paper read before the Chemical Society of Berlin, on January 15, S. Bogusky and N. Kajander, gave the results of their investigation upon the action of a number of acids upon Carrara marble. The paper had for its leading idea the rapidity of the evolution of carbonic anhydride and in the investigation five acids were employed, viz., hydrochloric, nitric, hydrobromic, formic, and acetic acids. The authors state that the first three of these acids obey a fixed law to the effect that the quantities of carbonic anhydride evolved in an unit of time are inversely proportional to the molecular weights of the acids. Formic and acetic acids, however, failed to show this regularity of action, apparently, as the authors state, in consequence of a physical change in the surface of the marble.

The communication is especially interesting, bearing as it does on the question of the time required for chemical action, and the meaning in nature of the relative weights of molecules. This is a subject which hitherto has commanded but little study at the hands of chemists, while it richly deserves serious investigation and would probably well repay workers in this direction. Without pausing to consider the well-known researches of Gladstone, Harcourt and Esson, and others on this subject, we may say that no method of inquiry in chemical science is calculated to throw so much light upon the nature of the chemical elements. We believe that useful and interesting results would be obtained by an investigation in which it was attempted to determine in what relation the atomic weights of metals stood to their chemical reactions, using on the one hand comparable salts or oxides, and a substance common to all on the other hand. Thus, when lime is added to chloride of manganese, chloride of calcium is formed, and protoxide of manganese is precipitated; the same is true of baryta and strontia, and it would be important to determine the amount of chloride of manganese decomposed by these various oxides and their hydrates under exactly parallel conditions, that is by using a definite amount of the chloride, and equivalent quantities of the oxides, etc. As in CaO, BaO, and SrO, the molecular weights differ only as regards the metal in each case, any difference in the results which might be obtained in the experiments indicated would, if the conditions observed in each case could be rendered absolutely parallel in all respects, be referable to such differences in the atomic weights of the metals. Or a similar series of experiments might be made with profit upon the various carbonates of the earths and sulphate of manganese.

We leave this interesting subject to direct attention to a paper also recently communicated to the German Chemical Society by E. Erlenmeyer. In this research the author has hit upon a simple method of preparing the alkaline cyanides as follows: potassic ferrocyanide (K_4FeCy_6) is fused with metallic sodium, when a colourless fluid mass is obtained, which, when poured off from the metallic iron that is also formed and allowed to cool, forms a snow-white mass containing 40 per cent. of cyanogen in combination with the alkaline metals. The reaction may be expressed as follows:

$$C_{12}N_{12}Fe_2K_8 + Na_4 = 8\,KCN + 4\,NaCN + Fe_2$$

The increasing employment of the vapour of nitrite of amyl in some spasmodic affections, and as an antidote to the action of chloroform, renders the administration of such a quantity only as is safe a matter of great importance, since a dose of vapour from five drops may save life, whilst that from twenty may destroy, or at least endanger it. With the view of having a safe quantity only ready for an emergency, it has been suggested to have four or five drops sealed up in a glass capsule, which may be readily broken in a piece of lint or the corner of a handkerchief, and the nitrite thus applied to the nostrils for inhalation. The suggestion has been carried out by Messrs. Allen and Hanbury.

APIOL.*

BY E. V. GERICHTEN.

During the preparation of oil of parsley by distillation of the seed with water, the so-called camphor of parsley or apiol separates gradually in fine needles. Homolle gave the same name to a mixture of different bodies obtained as a green-brown oil, by extraction of parsley seed with alcohol and ether, and the use of litharge; this is the "apiol" that has been recommended as a substitute for quinine in therapeutics. The author prefers that the name "apiol" should be confined to the crystallized volatile oil, which can also be obtained direct from the seed by extraction with alcohol, distillation, and digestion of the residue with ether, the apiol passing into solution whilst apiin remains undissolved. The author's experiments were made with apiol prepared by the latter method.

Apiol forms very long, white, efflorescent needles, having a faint smell of parsley. It melts at 30° C., boils about 300° C., and has a specific gravity of 1·015. It is not soluble in water, but readily so in alcohol and ether. When melted, apiol requires weeks or even months to become perfectly solid, but from solution in alcohol the original crystals can be easily obtained. The analytical results of various chemists find their simplest expression in the formula, $C_{12}H_{14}O_4$ (corresponding to $C=64·8$ per cent.; $H=6·3$ per cent., $O=28·8$ per cent.). By action of nitric acid upon apiol Martius obtained neither oxalic nor picric acid; Rump, on the contrary, obtained both acids. Lindenborn simply oxalic acid, no picric acid, and a yellow resinous body, which slightly deflagrated when heated on platinum foil, and appeared to be a nitrogenous body without acid properties. Sodium does not attack melted apiol. Concentrated sulphuric acid dissolves apiol with a blood red colour, and from this solution water separates a brown body, which dissolves in alkalies with blue-green colour that gradually passes into a dirty-brown. According to Lindenborn, a crystalline body cannot be obtained in this way. Strong aqueous potash solution does not attack apiol. But when heated twelve hours with alcoholic solution of potash, and water then added, rhombic scales, having a mother-of-pearl lustre, gradually separate; these can be purified by recrystallization from alcohol. No other special decomposition product was detected. The new body melts at 53·5° C., and solidifies again at 46° C.; it is not soluble in water, but readily soluble in alcohol and ether. It is not attacked by aqueous solution of potash. By careful oxidation with chromic acid, handsome acicular crystals, and with potassium permanganate scales are obtained; neither of these bodies have been further examined. The body obtained from apiol by alcoholic potash gives with chloroform and strong sulphuric acid at first a beautiful red-violet colour, gradually becoming green. It gave upon analysis in three experiments: $C=64·9$, $65·6$, $65·8$, $H=5·6$, $5·4$, $5·5$. When boiled with dilute nitric acid, it reacted energetically forming a yellow solution, from which when diluted with water and cooled there separated yellowish white crystalline flocks, oxalic acid remaining in solution. The flocks recrystallized from alcohol in beautiful long brilliant yellow needles, almost insoluble in hot water, and soluble in alcohol and ether. The crystals melted at 114° C., the fused mass rapidly solidifying again. In boiling potash solution, it dissolved gradully with an intensely purple-red colour; but was again completely precipitated from the solution in yellow flocks by carbonic acid. Nascent hydrogen (sodium amalgam) coloured the potash solution.

REACTIONS OF SALICYLIC ACID.

The following list of reactions for salicylic acid is quoted in *New Remedies* from an article by Dr. Richard Godeffroy in the *Zeitschrift* of the Austrian Apothecaries' Society:—

1. Salicylic acid, heated above its melting point, sp into *carbon dioxide* and *phenol*:

$$C_7H_6O_3 = CO_2 + C_6H_6O.$$

2. On distilling salicylic acid with excess of lime, *calcium carbonate* is formed and *phenol* distils over:

$$C_7H_6O_3 + CaO = CaCO_3 + C_6H_6O.$$

3. If salicylic acid is heated with *amylic alcohol* (fusel-oil) under pressure at 250° C., it splits likewise into *carbon dioxide* and *phenol*.

4. *Sodium-amalgam*, acting upon an acidulated solution of salicylic acid, which must be constantly kept acid, transforms it into *salicylous* acid:

$$C_7H_6O_3 + H_2 = C_7H_6O_2 + H_2O.*$$

5. Sulphuric acid dissolves salicylic acid without colour, and forms from it two isomeric *sulpho-salicylic* acids.†

6. On heating salicylic acid with dilute sulphuric acid and manganic oxide, *formic acid* is produced which may be distilled off.

7. Dilute sulphuric acid and potassium chromate likewise convert salicylic acid into *formic* and *carbonic acids* (Kraut).

8. On heating a mixture of sulphuric acid, wood-spirit

* Sodium-amalgam in contact with water takes oxygen from the latter to oxidize the sodium, and hydrogen is given off; the latter being in a nascent condition, *reduces* the salicylic acid by taking from it a portion of its oxygen to form water

† Ira Remsen, *Sill. Journ.*, 6.

(methyl alcohol), and salicylic acid, an agreeably aromatic liquid distils over, which is *methylic salicylate*.

9. Concentrated nitric acid converts salicylic acid at the common temperature into *nitrosalicylic acid*, $C_7H_5(NO_2)O_3$; dilute nitric acid produces the same result by heating.

10. Fuming nitric, or a mixture of concentrated nitric and sulphuric acids, converts salicylic acid, under violent reaction, into *picric acid*, $C_6H_3(NO_2)_3O$, and *carbonic acid*.

11. Chlorine and bromine produce *substitution products*.

12. Iodine acts upon a watery solution of the acid only when heated; if melted with dry salicylic acid, it produces *iodized substitution products* and a red amorphous body.

13. Warm hydrochloric acid dissolves considerable quantities of salicylic acid; on cooling or on dilution with water it separates again in brilliant white fine needles (Godeffroy).

14. Potassium chlorate and hydrochloric acid convert it into *chloranil* (tetrachlorchinon), $C_6Cl_4O_2$.

15. On heating salicylic with aqueous hydriodic acid to 280° C., *phenylic ether* and *carbonic acid* are formed.

16. On distilling it with phosphorus pentachloride, *chlorosalicylchloride*, $C_7H_4Cl_2O$ is formed.

17. If phosphorus trichloride be added to a mixture of salicylic acid and anilin, *salicylanilide* $C_6H_5NH(C_7H_5O_2)$ is produced.

18. Iodine and mercuric oxide acting on salicylic acid produce *iodized substitution products*.*

19. On mixing salicylic acid (3 mol.) with glucose (1 mol.), pouring over them a large excess of concentrated sulphuric acid, and gently warming, a fine blood-red colour is produced; this colour disappears after a while, and the mass turns brown and finally black.†

20. Caustic potassa solution dissolves salicylic acid readily; the solution soon turns brown in the air.

21. Watery solution of salicylic acid and its salts is coloured intensely violet by ferric salts. This reaction is so delicate that Aug. Vogel‡ has proposed it as a substitute for alkaline sulphocyanides as reagents for ferric compounds. In strongly acid solutions, however, this reaction does not take place. H. Weiske employs it as an indicator in alkalimetry.§

On evaporating the intensely violet solution containing salicylic acid and a ferric salt to dryness, the colour disappears entirely; but the least quantity of water restores it (Godeffroy).

22. Salicylic acid mixed with cupric sulphate and caustic soda solution produces a solution of an intensely bluish green colour, from which even a large excess of alkali fails to precipitate any cupric oxide.‖

23. Solution of sodium salicylate forms a grass-green liquid with cupric sulphate solution.¶

24. Silver nitrate produces a white precipitate in solutions of alkaline salicylates; but no precipitate in solution of salicylic acid.

25. Lead acetate behaves like the preceding.

26. On mixing a hot saccharated solution of simple calcium salicylate, Ca $(C_7H_5O_3)_2$, obtained from calcium carbonate and aqueous solution of the acid, with a boiling solution of caustic lime in saccharine water, a heavy crystalline precipitate of so-called *neutral calcium salicylate*, $CaC_7H_4O_3$, almost insoluble in water, is produced.**

27. If a solution of salicylic acid is boiled with a solution of potassium ferrocyanide, *hydrocyanic acid* is produced, and the liquid becomes turbid. This reaction is very delicate, and permits the detection of very small quantities of salicylic by means of the reagents for hydrocyanic acid (Godeffroy).

28. On boiling a solution of salicylic acid with a solution of potassium permanganate, the characteristic colour of the latter is immediately destroyed, and *carbonic acid*, *phenol*, and *brown hydrated manganic oxide* are produced.

CHLORAL WITH SOLID FATS.*

An anonymous writer in the *Med. and Surg. Rep.* says, as a therapeutic agent, chloral has become so popular that its range of application is as diversified as any drug or chemical of a century's standing; but its nature has not been sufficiently studied to construct formulæ readily that furnish preparations easily dispensed and always praiseworthy; on the contrary, formulæ are written which furnish not only inelegant, but almost incompatible preparations. A case in point is its combination with solid fats. It is a matter oftentimes overlooked, if not entirely unknown, that chloral hydrate is a solvent for fats, so much so, that solid fats become liquefied by contact. Hence, it is not advisable to prescribe, for instance, chloral with lard, simple ointment, or even with simple cerate, in a very large proportion. With oleum theobromæ it forms an unctuous mass, which furnishes a very creditable preparation dispensed as an ointment; but to make from this combination a suppository, is almost an impossibility. Still less possible is it to make a suppository containing, with chloral, one of the solid extracts, which must previously be moistened with a little water to make it miscible with the solid fat, as a drop of water increases enormously the fluidity of the oleaginous mixture. The writer has made a number of experiments as to the best excipients, and finds that equal parts of spermaceti and oleum theobromæ have the advantage over any other. In a suppository containing ten to twelve grains of chloral this is about the proper proportion. Deviating from this strength, the proportion of spermaceti must be increased or diminished accordingly. Vaseline and paraffin, using three of the former to two of the latter, make a very good base, but it does not melt as nicely into an unctuous mass as does the former.

NOTE ON THE ADMINISTRATION OF PHOSPHORUS.†

BY EDWARD R. SQUIBB, M.D.

It must be now admitted that phosphorus in its separate and elementary condition produces effects upon the animal economy which are not only different in degree, but also different in kind from the effect of phosphoric acids or any oxides of phosphorus. If the evidence for this statement does not yet amount to a demonstration, it is still entirely sufficient to justify the admission, and much too strong to be be disregarded. The deductions from Wegner's‡ researches alone, which have not been discredited, nor much weakened by his opponents—and which are mainly the results of improved and closer investigation of points well studied by his predecessors—are quite strong enough to be received as established for the present time. Mr. J. Ashburton Thompson§ gives useful testimony and much information upon the subject tending to the same conclusion. Indeed the entire drift of the medical literature of the past ten years has tended strongly in this direction, and has at the same time accu-

§ 'Free Phosphorus in Medicine.' By J. Ashburton Thompson, Surgeon at King's Cross, etc. London, 1874.

mulated a large amount of important experience and information too voluminous even for abstract here. Lemaire, besides his own work, summarizes the observations of Béhier, Lecorché, Dujardin-Beaumetz, Desnos, etc., and an abstract of his conclusions is given in the "Bulletin Générale de Thérapeutique" for September, 1875. Any one who may desire to follow the subject up to the most recent conclusions will find a very numerous and instructive series of papers and abstracts in the journal just referred to, and in the London *Practitioner*; and a good bibliography at the end of Mr. J. Ashburton Thompson's book.

A very much condensed summary of the present state of the therapeutics of phosphorus may be useful here, even though very imperfect. A very brief synopsis of the conclusions of Lemaire and the French authorities who preceded him may be given with the remark that the French are eminently conservative in regard to medication by phosphorus. Lemaire says, in substance, that in paralysis consecutive to acute diseases, or to "ataxo-adynamic" fevers; or in paralysis connected with alteration of the blood, as chloro-anæmia; or with diminution of the mass of blood, as from hæmorrhages, phosphorus has no special applicability; it is merely a tonic, or a stimulant of uncertain effect. Neither in cold paralysis, nor in hysterical paralysis, nor in that from cerebral softening, or from cerebral hæmorrhage, or from cerebral tumour, when these occur to any considerable extent. But if the clot be small, and the disturbance in the brain-substance not too great, phosphorus seems to hasten the cure even when the paralysis may have continued for a year. And in case of syphilitic tumors it may hasten the cure after the specific treatment shall have been successfully used. In old paraplegias it is useless; but in those of recent occurrence which may be incomplete and not dependent upon profound lesion, it seems to have a favourable influence. In recent cases of progressive locomotor ataxy where the affection has not become general it appears to be useful, sometimes in ameliorating the symptoms, and in certain cases arresting the progress, but it never cures. In flashing or shooting (fulgurant) pains it is very uncertain; and in impotence is very variable in effect, seeming only to strengthen the patient. In sclerosis and in lead poisoning it is entirely useless, but seems useful in poisoning from bisulphuret of carbon and from mercury. Its use in muscular paralysis of the eye, in incomplete amaurosis, and in amblyopia is so uncertain as to need farther observation, In sterility it gives uncertain results, and when useful it is sometimes long after the medication. Phosphorus, then, seems to be a stimulant and a tonic to the nervous system, and to be capable of benefiting some of the more profound nervous affections which it cannot cure. It should be used in all such affections only after the acute symptoms have given place to the chronic condition, and all active irritation has disappeared, and never during inflammation, fever or cerebral excitement. This rule is absolute, and when disregarded the condition will be made worse, even to a fatal termination.

The more effective applications of phosphorus seem to be to the functional derangements of the nervous system which are of an adynamic character, or, where organic or structural changes are slight, are temporary in character, or are just commencing. Structural changes which are preceded by functional disorder, or which produce functional disorder before the changes are fully established, and which are of a slowly progressive character, as, for example, those which arise from perverted nutrition, seem often to be within the entire control of phosphorus when skilfully applied.

But perhaps the most successful of all its applications is to that large class of cases wherein nervous power is used faster than the material for it is supplied, or to the condition which results in nervous exhaustion before the occurrence of serious structural change. Functional derangement is the effect of structural change as a cause. But structural changes differ in locality, in extent, in kind, and in degree. The remedial agency of phosphorus appears to apply most successfully to those changes which are general and not local, which affect the whole nervous system equably; changes of a kind which involve the relation of inferior supply to superior demand before the integrity of the tissues are seriously or profoundly invaded, or invaded to such a degree as to make retrogression very difficult. Tonic, sometimes to the extent of stimulation, and alterative from depressed conditions toward those of general health, it seems in the lower animals, at least, to have the special effect of increasing the gelatinous and bony structures (Wegner). It appears also to have a special therapeutic effect in some forms of neuralgia (Thompson), adynamic melancholia, in the nervous strain from overwork, and the nervous depression resulting from over-excitement. In this latter class of cases there appears to be nothing so generally successful in permanently but slowly relieving the prominent symptom of insomnia.

Phosphorus should be used with great caution, but not with timidity, and those who are afraid of it should let it alone rather than add to the large stock of so-called experience which has accumulated from imperfectly observed phenomena in its timid and unskilful application. It is dangerous only in the sense that all potent agencies are dangerous, because power to do good involves necessarily the same power for harm. The important peculiarity in regard to phosphorus, however, is that its poisonous effects from medicinal doses are remote, slow, and insidious; and and when allowed to go to an extent which does not appear very grave, the condition is irremediable. It is, except in small doses, cumulative in its action; and as for some uses it is given in increasing quantities, it should be suspended for a few days at the end of ten or twelve days, and then be resumed in smaller dose and increased as at first with the same watchful care. At the very first appearance of the slightest gastric derangement, such as gastralgia, vomiting or diarrhœa, it should be suspended, and be either abandoned, or resumed in smaller doses with increased watchfulness. The necessity for care is in proportion to the dose. From $\frac{1}{100}$th to $\frac{1}{40}$th of a grain three or four times in the twenty-four hours may be given for weeks and months even, without any extraordinary care; and although such are the doses most frequently required and used, they are not large enough for some of its uses. Doses as large as $\frac{1}{8}$th of a grain have often been reached, but $\frac{1}{12}$th is considered to be about the largest safe dose, whilst $\frac{1}{20}$th to $\frac{1}{30}$th of a grain need rarely be exceeded in the most active treatment to which phosphorus is applicable. These doses apply to the substance when in solution in cod-liver oil, where it is in its most effective and most uniform condition for use. When used in the solid form, however finely divided, or however combined, much larger doses are generally tolerated, but explosion in the effects much more liable. Doses of phosphorus in the solid form up to 3 grains have often been given without serious consequences. But acute poisoning and death rapidly follow the ingestion of larger doses, and often occur from much smaller quantities down to half a grain, and this in divided doses. The general drift of the best observations seems to show that the use of phosphorus in the solid form should be abandoned, because the dose has to be larger, and the results are uncertain and treacherous, because more or less of the solid substance may be dissolved in the primæ viæ, or more or less may pass off in an inactive condition, according to the condition of the stomach and the character of its secretions and its contents at the time of administration. In Continental Europe the common dose to begin with is a milligram, equal to $\frac{1}{60}$th of a grain, and this is given three to five times daily, and increased to say 5 milligrams, equal to $\frac{1}{14}$th of a grain. The dose and effects of phosphorus differ very much with the form in which it is given, and the causes of this have not been satisfactorily investigated. It seems to have been pretty clearly shown by Devergie, Solon, and Thompson, that its solution in vegetable oils is liable to develope poisonous properties, which render these variable and unsafe; and its is supposed that this is due to the formation of hypophosphorus acid, by a reaction between the phosphorus and certain elements of the oils, under the influence of light, air, and moisture. And even the method by superheating the oils before using them as solvents does not seem to render them unobjectionable. This excludes olive and almond oils, cacao butter, etc.

Solutions in alcohol, ether, chloroform, carbon disulphide, etc., though very easily made, are variable and constantly changing by reason of the volatility of the solvent, even though glycerine be added, while the pungency of the liquids, and the impossibility of diluting them with less pungent liquids without precipitating the phosphorus, render them difficult to administer. When such solutions are evaporated off in the formation of pills from them, oxidation of the phosphorus is unavoidable, and the lower poisonous oxide most likely to be formed. Beside, pills made by evaporation of the solvent have the disadvantages of those made from the subdivision of the solid phosphorus. A solution in resin is not very difficult to make, and affords a dry powder which may be dispensed easily, with the desired accuracy. But it is doubtful whether the same chemical change does not occur here that is known to occur with oil of turpentine, rendering the phosphorus comparatively inert. Besides, the resin is more or less difficult of solution in the stomach, and may, under conditions which are not improbable, carry the phosphorus through the alimentary canal without effect. Zinc phosphide, which at first appeared to offer a means of medication equal to free phosphorus, has not confirmed the expectations from it, while it is very difficult to make and control, difficult to know when well made or not, difficult to keep, and sometimes dangerous. From all that has been written upon the subject, it seems to be pretty well established that phosphorus should only be given in solution, and that the solvent used should be bland and not volatile, and should be capable of protecting the substance from oxidation for a reasonable length of time when kept from light and air. Such a solvent has been found in cod-liver oil, and the testimony in regard to the solution in cod-liver oil is, up to this time, so favourable as to indicate that all other preparations should be abandoned. It is, therefore, the object of this note to show that a definite uniform solution of phosphorus in cod-liver oil may be easily made and easily managed, so as to give an opportunity to the physician and pharmacist to use it with great accuracy and safety by ordinary extemporaneous prescription, allowing the physician to change his dose and mode of administration as each case may require in its different conditions and stages. This should put medication by free phosphorus under the same conditions for accurate administration and accurate observation with other potent remedies, and would enable physicians sooner to determine its true position and more accurate value in the materia medica by bringing it within their entire control and responsibility.

(To be continued.)

EARLY CLOSING AMONGST CHEMISTS AND DRUGGISTS IN NOTTING-HILL AND BAYSWATER.

A conference of chemists and druggists in the above districts was held on Thursday evening, February 15, 1877, in St. John's College, Moscow Road, Bayswater, under the presidency of Professor Redwood, for the purpose of considering what steps should be taken to shorten the present long hours of business.

The conference was opened by Mr. Henry Long, who stated at some length how the present movement had originated through the instrumentality of the Early Closing Association, which had again come into their neighbourhood, and, not being satisfied with the present state of things, had exercised its influence to form a committee, who hoped to carry out the object in view. For that purpose the meeting of that evening had been called, and Professor Redwood had been invited to preside.

The Chairman (Professor Redwood) then addressed the meeting and reviewed the whole question in a lengthy speech. He thought the subject demanded the serious attention of every one present. The Early Closing Association had effected great good in many directions, and he congratulated it upon the improvements already made. He called attention to the very exacting requirements from chemists and druggists, how they were liable to be called upon at all times, and the necessity of continual study. Modern education brought fresh knowledge, and therefore it was necessary that they should have sufficient time to keep up with that knowledge. He thought, therefore, it was their duty to reconcile the hours of business to the wants of the trade, and that duties which might be done in the day should not be carried on into the night. They should relieve those engaged in the business of that slavish application which distressed both body and mind. Great responsibility attached to pharmacists in dealing with deadly poisons, which must involve a great strain upon the mind. This being so, it called for a reduction of the present hours. The hours had been reduced in other trades, whilst in this that demanded so much study and attention an assistant was liable to be called up in the night, and had to work on Sunday. Now, how was this to be remedied? In the establishment in which he was first engaged in London, the hours were then from 7 a.m. to 10 and 10.30 p.m. But that same establishment now closed at 7 and 8, and the proprietor (Mr. Hills) assured him that the alteration had been effected by gradually initiating the public and medical profession into the change. If the gentlemen present did the like they would find that the work would be much better done in shorter hours. It had been found so in the city, in the banks and other large establishments, and he felt assured that if they reduced their hours of business they would reap great benefit in doing so. In conclusion he said he could not too earnestly recommend the subject to their serious consideration. The Chairman then called on Mr. Shirley to move the first resolution.

Mr. J. G. Shirley then moved and Mr. W. Matthews seconded the following resolution:—

> "Resolved, that in the opinion of this meeting, the hours of business which have hitherto prevailed amongst chemists and druggists are unnecessarily prolonged, and beyond what the public convenience requires, and this meeting believes that by a reduction of the hours the best interests of the employers and the employed would be promoted."

Mr. J. R. Faulkner moved and Mr. R. A. Johnson seconded the second resolution—

> "Resolved, that in order to promote an earlier hour of closing amongst chemists and druggists, this meeting recommends that a representative meeting of the chemists and druggists of the metropolis be convened."

Mr. H. Long moved and Mr. C. Butler seconded the third resolution—

> "Resolved, that the best thanks of this meeting be and are hereby given to the Early Closing Association for its valuable services in promoting the present movement and the cause of early closing generally."

Mr. W. Smith then moved and Mr. Horncastle seconded—

> "That the best thanks of this meeting be given to Professor Redwood for his kindness in coming to preside over it, and for his able conduct in the chair."

Several speeches deprecating the present protracted hours of business followed the resolutions. The Chairman then briefly returned thanks, and the meeting separated.

The Pharmaceutical Journal.

SATURDAY, FEBRUARY 24, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, *17, Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary, 17, Bloomsbury Square, W.C.*

THE BENEVOLENT FUND DINNER.

A LARGE proportion of our readers who watch with special interest the proceedings of the Council in relation to the Benevolent Fund will doubtless have made a note of the resolution passed on the 7th inst., that a Public Dinner should be held in aid of it next May. The appropriateness of this resolution at the present time will become apparent if it be borne in mind that ten years have elapsed since the last similar effort in aid of the Fund was made, and that ten years is the period during which Firms are entitled to votes on account of donations. The votes accruing for such donations made in 1867 have now therefore lapsed.

At the date of the last Dinner only two annuities had been granted and the Fund was only applicable for the relief of persons who were or had been connected with the Pharmaceutical Society. The provisions of the Pharmacy Act, 1868, have since then thrown open the benefits of the Fund to every Chemist and Druggist on the Register. The number of persons eligible for relief has therefore been increased from about 2000 to nearly 14,000, or sevenfold; and the number of annuitants, each receiving £30 a year, has increased from two to twenty-three. The net amount in aid of the Fund produced by the Dinner in 1867 was £1611 15*s.* 2*d.*; it does not, therefore, require a very abstruse calculation to ascertain what is the proportionate amount that should now be subscribed to meet the altered circumstances and increased liabilities of the Fund. It will be seen that in the item of annuities alone the expenditure has increased from £60 to £690, whilst the number of applications for assistance is unhappily largely increasing.

The fact that the administration of the Benevolent Fund of the Pharmaceutical Society is conducted almost free of expense will commend itself to the consideration of every business man, and it is a fact that the only charge on the Fund, on account of management, is for printing and for the paper and postage stamps actually used. It is not within our knowledge that there is a similar charity in existence from which so large a proportion of the amount originally subscribed reaches the hands of those for whom it was specially intended. We therefore, hope that when the list of stewards is issued it will be found to be thoroughly representative of all the interests connected with pharmacy.

POISONING OF PHEASANTS BY YEW LEAVES.

IN a letter to the *Field*, Professor TUSON recently stated that while examining a number of pheasants suspected to have been poisoned, he failed to detect any poison by the ordinary chemical tests, but in the craw and gizzard he found fragments of yew leaves and was therefore disposed to attribute the poisoning to this cause. Professor TUSON's letter prompted a communication from Mr. COSENS, of Cwm, stating that on more than one occasion he had met with similar cases, but in his experience the fragments of leaves contained in the crops and gizzards of the birds were always those of Irish yew alone, and the birds were found dead close by the only two Irish yews in the wood, through it abounded in the English variety. Mr. COSENS therefore suggested whether perhaps pheasants might feed with impunity on the common yew, but not on the Irish variety. Unfortunately for this theory, Professor TUSON is able to say that the leaves found in the birds examined by him were those of the Irish yew. We are glad to note that Professor TUSON has undertaken to investigate the whole subject of poisoning by yew.

FIRE AT A COLLEGE OF PHARMACY.

WE regret to learn that on the 22nd ult., the Massachusetts College of Pharmacy sustained a very severe loss by fire. It appears that the lectures have been delivered, since the beginning of the present year in the third floor of a building belonging to the municipality of the city of Boston, who had generously given the accommodation to the College. The second floor was unoccupied, and the ground floor was used as one of the city ward-rooms. The fire appears to have originated in the overheating of some hot air pipes immediately over two furnaces in the basement and spread rapidly to the lecture room, where it destroyed all the cases containing the specimens of drugs and chemicals with which the room was fitted. The total loss to the College is estimated at about 3000 dollars, which is but partially covered by insurance. But the Boston pharmacists do not appear to have considered the disaster an overwhelming one, as it did not prevent them from holding a "banquet" in connection with the annual meeting of the local association two days afterwards.

A TRIAL OF XANTHIUM SPINOSUM.

SOME experiments recorded in the *Archives Vétérinaires* appear to demonstrate, what has been feared from the first, that *Xanthium spinosum*, which has already begun to figure in the brokers' catalogues, will have to be dismissed to the limbo of unsuccessful specifics against hydrophobia. The experiments were made in the chemical school at Alfort, by MM. TRASBOT and NOCARD. Eleven dogs were carefully innoculated with saliva from another suffering from hydrophobia; to six of these were administered doses of xanthium in proportion to their weight, whilst the other five were left to the unrestrained virulence of the saliva. The first dog to show signs of madness, on the thirteenth day after innoculation, was one of those to which xanthium was administered, and it died on the fourteenth day, after having taken 125 grams of the powder. During the next fifty days, seven more dogs died, but without presenting hydrophobic symptoms sufficiently decided to be taken into account. On the eightieth day another dog died with all the symptoms of hydrophobia. This beast had been bitten also by the first dog that died, therefore although it weighed only 4·5 kilograms, had had 10 grams of xanthium powder administered to it daily for twenty-five days after innoculation. The experimenters therefore express an opinion that *Xanthium spinosum* has not the property of curing hydrophobia or of preventing its development after either artificial or natural innoculation.

DEATH OF PROFESSOR CARSON.

IN the American journals just received is recorded the death, on the 30th December, of Dr. JOSEPH CARSON, the President of the last convention for the revision of the United States Pharmacopœia. Dr. CARSON was formerly Professor of Materia Medica in the Philadelphia College of Pharmacy and afterwards held a similar appointment in the University of Pennsylvania. For nearly fourteen years—from 1836 to 1850—he was the Editor of the *American Journal of Pharmacy*.

THE Deputation appointed by the Council in November last to wait on the Commissioners of the Treasury in reference to the application of the penalties recovered under the Pharmacy Act had an interview with the Secretary to the Treasury, Mr. W. H. SMITH, on Monday, the 12th inst. We understand that the result of the interview has been favourable.

THOSE pharmacists who have been in the habit of using Messrs FINZEL's sugar crystals will be sorry to read the announcement that the extensive sugar refining establishment at Bristol is to be closed after this week. The cause of the stoppage, according to the *Echo*, is attributed to the scarcity of the raw material and the influence of the French drawback system. It is said that two thousand workpeople will be affected by this decision.

Provincial Transactions.

CHEMISTS AND DRUGGISTS' TRADE ASSOCIATION.

A meeting of the pharmaceutical chemists and chemists and druggists of Edinburgh and district was held on the evening of Tuesday the 13th inst., at St. Andrew's Square, Edinburgh, for the purpose of hearing addresses on the claims of this Association on chemists and druggists. Mr. George Blanchard occupied the chair, and upwards of thirty persons were present. After the Chairman had made some introductory remarks he called upon Mr. Barclay, of Birmingham, to address the meeting.

In the course of a lengthy speech Mr. Barclay referred to the correspondence which appeared in the *Pharmaceutical Journal*, between the Secretary of the Association and the Secretary and Registrar of the Pharmaceutical Society. There seemed to be a feeling, he said, that there was a little *animus* existing in the minds of some of those who were at the head of this Trade Association, in reference to the Pharmaceutical Society. He could not understand why such a feeling should exist, and he felt sure that none connected with the Trade Association had done anything to warrant it. Every action of theirs was scrutinized, and if there appeared to be anything that could be laid hold of it was pointed out with great glee. The Law Committee of the Trade Association assumed that the Pharmaceutical Council would examine the evidence, as it is supposed they do in all cases, as through the Registrar they are the only prosecuting party, and if they considered it all that was necessary, the question was, Would they instruct their solicitor to go forward and prosecute? The reason the question was put was this: Mr. Haydon was not a paid agent of the Pharmaceutical Society, and therefore they wished to know whether the Council would make use of the evidence of the Trade Association in obtaining a conviction. Mr. Bremridge's answer was to this effect: "I have further to say that any evidence of infringement of the Pharmacy Act, 1868, forwarded to me, will be submitted to the Council." Now would they, he asked, take that to be an answer? The Law Committee of the Association, through Mr. Haydon, said, in answer to that communication, that the reply was not satisfactory, and then the Secretary of the Pharmaceutical Society wrote, on his own responsibility, and asked for particulars of the cases. Mr. Haydon had previous instructions to obtain a reply to the original question before forwarding particulars, and consequently replied that his instructions prevented his complying with Mr. Bremridge's request. The result had been that they were blamed by some members of the Pharmaceutical Council, who had also remarked "to think that they should go forward and prosecute at the dictation of this Trade Association." He could scarcely understand how any men could take that position, as the Council, and the Council only, were responsible to the public and the chemists of the country for such prosecutions, and it was but a poor tribute to the common sense of the Trade Association to think they should ask such a thing. However, if the Law Committee of the Association had stated the matter a little more fully it would have saved trouble and at the same time if the Pharmaceutical Council in their reply had done the same thing they would have understood each other better. It should, however, be mentioned that the resolution of Mr. Bottle was perfectly clear, and this was passed without any further light on the subject. If this had been sent in reply to the first letter of the Secretary of the Association much of the correspondence would have been avoided. The Trade Association acted in no officious spirit, but to make things work as smooth as possible; they were all desirous of promoting the best interests of the chemists of the country and had the same goal in view.

The proceedings were terminated by the passing of a resolution approving of the objects of the Association, and a vote of thanks to the Chairman.

At a meeting of the Law Committee of the Chemists and Druggists' Trade Association, held on Friday, the 16th inst., the following resolutions were unanimously passed:—

"That the Solicitor be instructed to defend a member of the Association in an action commenced against him under the Medical Act, 1815, and to take such means for that purpose as he shall think fit."

"That the Secretary be directed to acknowledge the resolution passed by the Council of the Pharmaceutical Society, at its meeting on the 7th inst., which clearly answers the question put by the Secretary of the Association in his letter of November 27, 1876, and at the same time to inform the Council that the previous letters of this Committee have been misunderstood as this Committee had no intention of forcing upon the Council any cases, but simply of supplying, as they stated, such evidence as the Council might deem necessary if the Council on its part was willing to make use of the same."

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, February 13, 1877, Dr. J. H. Gilbert, F.R.S., Vice-President, in the chair. The names of the visitors having been announced, and the minutes of the previous meeting read and confirmed, the names of Messrs. A. Angell, F. W. Young, E. W. Napper, and H. G. Stacey, were read for the first time. Messrs. Michael Conroy, Arthur Pearson Luff, John Angell, Joshua Bardsley, Matthew Algernon Adams, and Peter Townsend were balloted for and duly elected after their names had been read the third time.

The Chairman, in accordance with the bye-laws, announced the proposed changes in the council and officers of the society for the ensuing year. It was proposed to elect Dr. J. H. Gladstone as President in place of Professor Abel, who retires. The Vice-Presidents are Mr. Field and Dr. Roscoe, in place of Mr. Longstaff and Dr. Gladstone. The other members of council are Messrs. Lowthian Bell, C. E. Groves, W. N. Hartley, T. Hyde Hills, and G. Matthey, in place of Messrs.. D. Campbell, J. Dewar, F. Field, N. Story Maskelyne, and W. Valentin.

The first paper was by Dr. A. Dupré, "On the Estimation of Urea by Means of Hypobromite," the object of the communication being to describe a form of apparatus which could be conveniently worked, and such modifications in the preparation of the hypobromite solution as to prevent the escape of any bromine vapour, so that the process might be used in the wards of a hospital. The apparatus consists of a crucible inverted in a tall cylinder of water, and connected by a side-tube with the generator by means of a long piece of caoutchouc tube. The generator containing the proper quantity of hypobromite is a bottle closed by a vulcanized cork, through which passes a short tube to connect it with the burette, and also having a small test tube attached to it to contain 3 c.c. of the urine under examination. After the cork has been firmly inserted, the urine is mixed with the hypobromite by gently shaking the generator. The latter is briskly agitated for a short time, and then plunged into cold water. After allowing the apparatus to stand a few minutes to cool the gas to the same temperature as the water, the level of the liquid inside and outside the burette is made the same by raising the latter, and the reading of the gas taken and also of the thermometer. The necessary quantity of hypobromite is easily prepared by pouring into a stoppered cylinder enough caustic soda solution (100 grains to 250 c.c. of water) to fill it up to a 25 c.c. mark on the side, introducing a thin sealed tube, containing 2·2 c.c. of bromine, and agitating briskly, so as to break the thin tube. The amount of nitrogen given off is found to be 91 per cent. of the total quantity in the urea, and the burette may be so graduated that it gives readings of the percentage of urea at the normal presence and temperature.

The Chairman said they were much indebted to the author for facilitating the process of the estimation of urea, one of the most important in hospital practice, as showing the amount of nitrogen eliminated by the renal organs. Although urea represents nearly all the nitrogen in the urine of the human subject, this was not the case with the ruminants.

Dr. C. R A. Wright remarked that in some experiments on this method of determining urea, made in his laboratory, by Dr. Blackley, a slightly higher percentage of nitrogen had been obtained, about 93 per cent. The apparatus described by Dr. Dupré possessed considerable advantages over those of Russell and West and of Dr. Blackley, as there was no danger of spilling the corrosive hypobromite solution if ordinary care were taken; at the same time in agitating the generator the latter might get heated, and thus increase the reading.

Professor Hartley suggested the substitution of a gutta percha tube, for holding the urine in the generator in place of the fragile glass one.

The next communication was on "A New Carbometer for the Estimation of Carbonic Anhydride," by Mr. S. T. Pruen and Dr. G. Jones. It is somewhat similar to Scheibler's "calcimeter," consisting of two equal graduated glass tubes filled with water, on the surface of which a layer of oil floats, and connected with each other by a piece of caoutchouc tubing. One of these is raised or lowered automatically, the other is fixed and connected at its upper extremity with the generator by means of india rubber tubing, a chloride of calcium tube being interposed between the generator and the measuring tube. The generator consists of a small flask, in which a weighed quantity of the carbonate under examination is placed, together with a small gutta percha tube containing hydrochloric acid. The decomposition is effected in the usual way, and the evolved gas measured, the barometric pressure being taken, and the temperature observed by means of a thermometer in the measuring tube. Tables of data for the necessary corrections accompany the paper. The authors state that it is more convenient than Scheibler's apparatus, as it is less cumbersome, the tubes do not require refilling or emptying, and it is self-acting.

Mr. Warington observed that there was a source of error in the Scheibler instrument which also attached to this apparatus, namely, that the correction to be applied for the carbonic anhydride dissolved by the hydrochloric acid was the same, whatever the percentage of carbonic anhydride, whereas if there were much air and comparatively little carbonic anhydride in the flask at the close of the experiment, the hydrochloric acid would absorb but little of the carbonic anhydride, whilst if the air were rich in carbonic anhydride, the acid would absorb more of the latter.

Dr. Dupré called attention to the fact that although the gas was dried by passing over the calcic chloride, it must become moist by contact with the moist sides of the measuring tube, to which Dr. Jones replied that it was found practically that the film of oil prevented the gas from coming into contact with the water and thus becoming moist.

The next paper was "On the Influence exerted by Ammonium Sulphide in Preventing the Action of Various Solutions on Copper," by F. W. Shaw and T. Carnelly. Clean pieces of copper foil of known surface were coated with a thin film of sulphide by immersion in dilute ammonium sulphide, and subsequently thoroughly washed. The results of the action of distilled water and of various solutions on these as compared with similar pieces of clean copper are given in a series of tables, from which it appears that the film of sulphide does not lessen the action of distilled water, but, on the contrary, increases it, both at the ordinary and at elevated temperatures; this is due to the oxidizing action of the air, as shown by the results obtained in closed flasks, completely fitted with water that had previously been well boiled. In the case of saline solution the film of sulphide lessens the action on the metal; the salts experimented with being potassic nitrate, sulphate, and carbonate, sodic chloride, nitrate, and carbonate, magnesic sulphate, and ammonic chloride, nitrate and sulphate.

The Chairman having thanked the authors, the Secretary read "An Experimental Inquiry as to the Changes which occur in the Composition of Waters from Wells near the Sea," by Mr. W. H. Watson. The well examined was about nine feet deep, the bottom being twenty-four feet above the level of the sea, and was situated at Braystones near Whitehaven, about half a mile distant from the sea. Determinations of the chlorine were made each day, the water being collected at about 10 A.M., and the results are given in a table. The amount of chlorine varied from 5·95 to 17·50 grains per gallon, whilst the other constituents, such as sulphates, remained almost constant. The author considers the variations observed in the water of this well situated in an alluvial soil to be due chiefly, but not entirely, to the weather, as from the nature of the intervening strata, it may be directly subject to infiltration of sea water.

Mr. F. Maxwell Lyte said that he had examined the mineral water at the Source de Salut Bagnières de Begorre during many years, and had found that from October to December an extraordinary change took place in the nature of the water, as it became sulphurous, and the quantity of salts in it increased. It was probable that the deep spring was sulphurous, but became altered by the infiltration of other springs near the surface, which after the droughts of summer partially dried up; thus the supply of oxygen being partially cut off the spring resumed its sulphurous character.

Mr. C. E. Groves remarked that springs in alluvial soils near the sea might derive much of their chlorine from the acid driven over the land in stormy weather, and which, settling on the land, was washed in along with the surface water by subsequent rains.

The Chairman, in thanking the author, said it was necessary to know all the circumstances connected with the well before the source of the large amount of chlorides in it could be definitely accounted for.

"On the Solvent Action of various Saline Solutions on Lead," by Mr. M. M. P. Muir. The author, from an examination of the action of various saline solutions on lead, infers that in the first place a soluble salt of lead is produced, which by the action of carbon dioxide, absorbed from the atmosphere, is slowly converted into hydrocarbonate, in which form it is to a greater or less degree precipitated. In certain solutions, especially those containing ammonium nitrate and calcium chloride, the formation of the soluble lead salt proceeds more rapidly than its precipitation as hydrocarbonate, although after long periods the latter action preponderates. Lastly, carbonates reprecipitate the soluble lead salt in the forms of hydrocarbonate as fast as it is produced. A table showing the solubility of lead hydrocarbonate in the saline solutions examined is appended to the paper.

The Chairman having thanked the author, two other papers were read by the Secretary, the first being a preliminary notice on "The Derivatives of Di-isobutyl," by Mr. W. Carlston-Williams. The di-isobutyl employed in the investigation was prepared by the action of sodium on isobutyl bromide, and boiled at 109° C.; submitted to the action of chlorine, it yielded a liquid possessing an odour resembling that of the orange, and consisting of a mixture of iso-primary and iso-secondary octylic chlorides, boiling at 170° to 180°. The mixed chlorides, heated with potassic acetate and acetic acid at 200°, yielded besides the octylic acetates, an octylene, boiling at 122°, and which had a specific gravity of 0·7526 at 16°. The mixed acetates boiled at 193°–205°, and by treatment with potassic hydrate, were converted into a mixture of the primary and secondary octylic alcohols, boiling at 175°–187°, the quantity of which was too small to permit of any attempt at separation. It was, therefore, oxidized by potassium dichromate and sulphuric acid, when it yielded iso-caprylic acid and an acetone, which on further oxidation split up into acetic and carbonic acids. From these results it would seem that the secondary alcohol is isopropylisobutylcarbinol,

$$CH(CH_3)_2{\cdot}CH(OH){\cdot}CH_2{\cdot}C(CH_3)_2,$$

whilst the primary alcohol may be represented by the formula:—

$$CH(CH_3)_2{\cdot}CH_2{\cdot}CH_2{\cdot}CH(CH_3){\cdot}CH_2(OH).$$

The isocaprylic acid is an oily liquid, somewhat resembling valerianic acid in odour. Its silver salt is slightly soluble in boiling water, and is deposited on cooling in minute tooth-shaped crystals; the barium, lead and zinc salts are amorphous, but the calcium salt is characteristic, crystallizing in plates radiating from a central point. It is less soluble in hot than in cold water, so that on raising the temperature of a solution saturated at 15° to 36° C. the salt is precipitated.

"Notes on Madder Colouring Matters," by Dr. E. Schunck and Dr. H. Roemer. The first of these describes a method of detecting small quantities of alizarin in mixtures of alizarin and purpurin by exposing the solution of the substance in caustic alkali to the air until it has become almost colourless; the purpurin is thus decomposed, and on agitating the acidified solution with ether the alizarin is taken up and may be recognized in the usual manner by its absorption spectrum. The second note is on "Purpuroxanthic Acid, a colouring matter found in commercial purpurin," from which it was separated by boiling it with alum liquor, precipitating by hydrochloric acid, and extracting the precipitate with alcohol; a residue containing alumina was left which gave purpuroxanthic acid by crystallization from alcohol mixed with a little hydrochloric acid. This acid may also be obtained from the alcoholic mother liquor obtained in crystallizing commercial purpurin, by evaporating them, boiling the residue with water and adding hydrochloric acid to the filtrate, which throws down the impure purpuroxanthic acid as an orange precipitate. It is purified by boiling it with baryta, which dissolves the impurities and leaves the acid as a baric salt. Purpuroxanthic acid, $C_{15}H_8O_6$ or $C_{14}H_7O_4$,COOH, crystallizes in yellow lustrous needles or scales, which are easily soluble in alcohol and acetic acid, and far more so in boiling water than most madder products. It melts at 231°, and at 232°–233° C. decomposes, giving off carbonic anhydride, and leaving purpuroxanthin, $C_{14}H_8O_4$, no other substance being produced. Purpuroxanthic acid dyes alumina and iron mordants orange and brown respectively, but the colours are very fugitive.

The Chairman, having thanked the authors, adjourned the meeting until Thursday, 1 March, when there will be a lecture by Professor T. E. Thorpe, "On the Theory of the Bunsen Lamp."

SOCIETY OF ARTS.

Zinc White as Paint, and the Treatment of Iron for the Prevention of Corrosion.*

BY PROFESSOR BARFF, M.A.

White Lead.

Some years ago, when I first had the honour of delivering a course of lectures before this Society, my subject was artists' colours and pigments. In those lectures I pointed out very earnestly the great objection I had to white lead as a pigment for artists. The following reasons which I then assigned for its disuse I have still

* From the *Journal of the Society of Arts*, February 16, 1877.

further confirmed by long experience. First, white lead is discoloured by sulphuretted hydrogen, which is known as foul air. In small quantities sulphuretted hydrogen changes the tint of white lead to that of a dirty brown colour, and in larger quantities it blackens it completely. It is manifest that such a pigment ought never to be employed where the permanency of a delicate tint is desired and where foul air can have access to the painting in which it is employed. Another reason I then explained was, that oil with which lead is ground up is decomposed, first, by the action of the oxide of lead in the white lead, forming a lead soap known as lead plaster; and further, after the lapse of a long time, an interchange takes place between the acids of the oil and the acid of the carbonate of lead; take for example the oleic acid and the carbonate of lead forming oleate of lead, which is, in fact, lead soap. I shall presently show you a specimen of lead soap, and you will be able to distinguish the difference of opacity between it and lead paint; therefore, if lead paint, that is, carbonate of lead, loses its opacity, it loses that quality for which it is so much valued. It is true that a saponification of the oil by the oxide of lead and the carbonate of lead gives to the paint at first a quality for which it is much valued; and this quality consists in the facility with which the workman can lay it on, and make it cover the ground which it is intended to conceal. But this very change, which in the first instance is an advantage, brings about future calamity, for the saponification increasing, the transparency of the pigment also increases, and so at last that which it was intended to conceal, again reveals its existence through it. I do not intend this evening to enter upon the subject of white lead manufacture. I have, on one or two occasions, very fully explained it in this room, and other gentlemen in treating on subjects in which it occurs have also treated its manufacture in an exhaustive manner. It is enough for me to remark that wherever white lead comes in contact with the digestive organs of a human being, whether it be by passing in a state of fine division into the mouth, and thence out, as it must do, without excessive precautions, into the system—in places where white lead is manufactured and ground—or through the carelessness and want of cleanliness of painters, who eat their meals with hands sullied by noxious materials, so that it passes into their system, it produces the same disease, which is known by the name of "lead-poisoning." Experience tells us that many, even most, men will for temporary ease run the risk of future pain and calamity. It is all very well to say that precautions are taken to save men from the consequence of their carelessness and indulgence. Similar precautions are taken in coal-mines, which if attended to would prevent the awful calamities which so frequently result from their neglect. We must not content ourselves with these precautions when we can, if we choose, do away with the danger altogether. It is clear we cannot give up the use of coal, but now we can give up the use of white lead in those employments where it is injurious to the health of the employed; and nothing but a miserable prejudice, and what is worse, a miserable clinging to commercial interests, can stand in the way of this reform, which, I believe I can show you to-night, will not require any sacrifice on the part of those who use this material for the decoration, cleaning, and beautyfying of the houses in which they dwell. I have to introduce to your notice a zinc pigment, which possesses nearly, if not quite, as good a body as the best white lead, and which will neither turn brown nor blacken by the action of foul air, nor will it become semi-transparent, as I have already shown you white lead does.

The processes of its manufacture have been patented, and it is now being made on a large scale for the inventor, Mr. T. Griffiths, of the Silicate Paint Company, Liverpool. It has for its basis the white sulphide of zinc, a precipitate well known to chemists in their analysis, but one which usually presents a most dingy and uninviting appearance in the test-tube. It was found, however, that this precipitate, properly treated, possessed what painters term "body," and the problem to be solved was, how to prepare it pure in tint. Like most important inventions, the first laboratory experiments were disappointing and unsatisfactory. It was attempted to precipitate pure sulphate of zinc by pure sulphide of sodium. But it was found that, even after several crystallizations, the zinc sulphate still retained sufficient impurities to injure the brilliancy of the white, and the sulphide of sodium was liable to the same objections. For a time this was abandoned. Sulphuretted hydrogen was tried, the zinc solution being made alkaline as it became acid. It is well known to chemists that zinc frequently contains traces of cadmium, which it is very difficult to remove. The cadmium at once showed itself in this method, being precipitated as a yellow sulphide. Of course, the cadmium might have been easily removed by saturating the acid zinc solution with the gas and filtering from the precipitate thus formed; but the process had the great objection of being too expensive for large manufacture. Sulphide of calcium was found to answer well as a precipitant; but, for some unexplained cause, the product lacked "body." It was determined to try sulphide of sodium on a large scale, no attempt being made to purify the zinc solution, and the sulphide of sodium only being allowed to deposit such solid matters as did not remain in solution. Strange to say, the zinc sulphide precipitated was perfectly white, and the original impurities remained in solution. The washed and dried precipitate, although having better body than ordinary zinc white, still fell far short of white lead in this quality, and calcination was resorted to to remedy this. The result was satisfactory as regarded body, but the pigment acquired a yellow tint, which could not be removed; besides this, it acquired a degree of hardness which necessitated much grinding to make it fit for use as paint. If the particles of zinc sulphide could be kept asunder in the process of calcination, this might be remedied. Sulphate of barium promised well for this purpose, and it was accordingly tried. Zinc sulphate was first precipitated by sulphide of sodium, and to the mixture was added a certain proportion of chloride of barium. The resulting precipitate of sulphate of barium was intimately mixed with the first precipitate of sulphide of zinc, and the washed precipitates were subjected to a red heat for several hours in a reverberatory furnace. On examining the product it was found to be excellent as regards body, far better than the sulphide of zinc alone, in fact quite equal to while lead, and the tint was pure. These results were most satisfactory, and it was clearly shown that sulphate of barium was far from being detrimental, and therefore could not be looked upon as an adulterant. One quality was still wanting, "softness." The product, when ground with oil, did not work kindly under the brush, but had a tendency to drag and become streaky. Many remedies were suggested to obviate this, but for various reasons had to be rejected. It was found, however, after much experimentation and research, that magnesia in small quantity imparted this quality of softness to the pigment and caused it to unite kindly with oil. This admixture was effected in the precipitating vats along with the sulphide of zinc, and no doubt saponification is brought about between the magnesia and the oil similar to that produced by white lead and oil, but not to the same extent, and thus ease in working is imparted to the paint. This pigment is now being manufactured on the principles I have described, such small modifications only being introduced as the growing knowledge of the peculiarities of the process suggest.

Iron.

While experimenting, two or three years ago, with my friend, Mr. Hugh Smith, on different methods for preventing incrustation and corroding of steam boilers, I was led, through the failure of all the processes employed, to believe that, if it were possible to convert the surfaces of iron plates into the magnetic, or black oxide of iron, in such a manner that the particles of black oxide formed in the position of the original particles of iron could be rendered perfectly adherent to the iron surface, which does not become peroxidized, and perfectly coherent with one another, the object would be effected. I do not intend to enter into the chemistry of the oxidation of iron to its full extent; it would take too much time, and it would rather tend to confuse than to enlighted those who are not well up in their chemistry, and would raise questions which would bring on prematurely a collision with the views of some of my brother chemists, which collision, under suitable circumstances, at some future time, not very remote, I look forward to with considerable satisfaction, as it will be the means of solving many phenomena which have never yet been explained. A piece of dry iron, its surface being polished, may be exposed for any length of time to dry air without rusting, but it begins to rust at once as soon as the slightest moisture comes in contact with it. We have to consider only two oxides of iron: one containing 56 parts by weight of the metal to 16 parts of oxygen, and the other containing twice 56 parts of iron and three times 16 parts by weight of oxygen. We speak of these oxides as the protoxide and sesquioxide, or as ferrous and ferric oxide.

Immediately the protoxide is formed, it being more moist, it unites with oxygen and becomes gradually converted into the ferric oxide. Now, let us suppose a moist iron plate to come into contact with oxygen. It is clear that the protoxide will be first formed, and this rapidly becomes converted into the higher oxide. Now, suppose you take a solution of the salt of the higher oxide and put into it metallic iron, in time, the air being excluded, this higher salt will become converted into a salt of the lower oxide. Let us now see how this bears upon the rapid oxidation of iron in the presence of moisture. We have seen that when oxygen comes in contact with moisture the first oxide is formed and becomes rapidly oxidized into the higher one. But this higher oxide is in contact with metallic iron, which will reduce it to the lower oxide, thus becoming oxidized by the oxygen which it has taken up from the higher oxide. You will now see clearly how it is that iron rusts throughout its whole substance with such rapidity, for the oxide of iron serves as a carrier for atmospheric oxygen to the iron to almost any depth. There is another oxide of iron, called the black or magnetic oxide, containing three times 56 parts by weight of iron and four times 16 parts by weight of oxygen. Some chemists consider this oxide to be a sort of mixture of the two others, and they call it ferroso-ferric oxide; whether this be the case or not does not matter to us this evening. But it is a most important point for our consideration, that this oxide undergoes no change whatever in the presence of moisture and atmospheric oxygen. Nor does any temperature to which it can be exposed, in any of the ordinary uses to which iron is applied in the presence of moisture, either decompose it or produce its further oxidation. In every school where chemistry is taught, in the most elementary lecture on hydrogen the pupils are told that if they pass steam over red-hot filings contained in an iron tube, they will be able to collect and burn hydrogen gas at the opposite end of the tube to where the steam enters. For a long time it was thought that the particles of black oxide formed by this decomposition of the steam were pulverulent, and could not be made to cohere into a solid mass. The result of a considerable number of experiments has been to prove that they can be made not only coherent amongst themselves but adherent to the body, and that both these produce a proper formation of this black oxide on the surface of iron plates; for, as I will show you later on, the oxidized surface of the iron resists for a long time, and more effectually, the rubbing with emery paper, than does the simple metallic iron itself, and that there is a very manifest difference between the ease with which a sharp rasp is able to cut away the surface of the iron, and the difficulty with which this black oxide is removed from the surface by that same instrument. The method which long experience has taught us is the best for carrying out this process for the protection of iron articles in common use, is to raise the temperature of those articles, in a suitable chamber, say to 500° F., and then pass the steam from a suitable generator into this chamber, keeping these articles for five, six, or seven hours, as the case may be, at that temperature in an atmosphere of superheated steam. I will presently call your attention to the diagram of the furnace and muffle which I have employed in all our later experiments, and in which all the specimens before you, which will be alluded to in this paper, were prepared. Differences of temperature are employed where different objects are to be obtained. If it be wished to act upon surfaces of polished iron or steel, it is desirable to let the temperature remain at 500° F., until the operation is completed. Articles coated in this way will not resist the action of continued moisture such as has prevailed for the last two months, when exposed out of doors; but they will resist the action of any amount of moisture with which they may come in contact in a house or building; and the reason of this will be very obvious, because only a thin film of the iron on its surface is transformed into the black oxide. This I will explain more fully to you, when I call your attention to individual specimens. At a temperature of 1200° F., and under an exposure to superheated steam for six or seven hours, the iron surface becomes so changed that it will stand the action of water for any length of time, even if that water be impregnated with the acid fumes of the laboratory. Before calling your attention to our failures and successes as they lie before you on the table, I will just allude to a few of the uses to which this process may be, as I consider, successfully applied—to water-mains, also to water-connecting pipes, as well as to the water-pipes used inside the house, which, in this case, would supplant their leaden predecessors. In this hall of hygiene, these words will, doubtless, sound as sweet music to the ears of many of those who have honoured me with their attendance this evening. The greatest objection to the use of iron pipes for the supply of water in houses hitherto has been this, that by rusting they caused the first quantities of water drawn off in the morning to be dirty and turbid; now this will be entirely prevented, if the pipes be first exposed to the treatment which I have just explained to you—of course gas-pipes could with advantage be similarly acted upon—and as the surface, when oxidized, is harder than the natural surface of the iron, the friction of large bodies of water through the pipes, and the friction necessarily employed in fixing them in their places, would be much better resisted than by the untreated iron itself. I cannot over-estimate the advantages which the employment of this process must confer on architects, who will be by it enabled to employ iron, whether wrought or cast, much more largely, not only in the decoration but in the construction of their buildings. Last summer I was at a very large house in the country, where the entrance portico, some twenty feet high, was being painted and decorated, when one of the large plaster ornaments of the ceiling broke away from its holdings, and would have fallen to the ground except that it was caught by a workman. This ornament weighed not less than twenty-five pounds, and if it had fallen from this height upon the workmen below it must have killed them. The ornament had been there many years, and was fixed up in the best method possible, it being supported and secured by iron rods. On examination I found that these rods were rusted through completely to the very centre. I need not make any comment upon this, since I have been able to introduce you to iron treated in such a way that it will never rust. Of course if the process will answer for architectural ornaments, it will answer for statues, so that iron may be used instead of bronze, which will materially lessen the cost of casting statues, both in the material and in the expense of making the moulds. You well know that when a tinned saucepan is allowed to get dry on the fire and burns, as the servant calls it, that it is rendered useless until it is tinned again. Now, if such a saucepan be treated by the method I recommend it may be allowed to get red-hot without suffering injury, for the protection on its surface is produced at a red heat. We have experimented on some screws, hinges, locks, keys, bolts, with complete success. It has been suggested to me that the iron nipples used in gas-lights would not corrode, and would, therefore, be more useful, if submitted to this action of superheated steam. Wherever iron is used, railings, street gas-posts, iron safes for keeping documents fire-proof and thief-proof, the framework of filters, tanks, cisterns for domestic and other uses, iron employed in the erection of temporary buildings—which, I flatter myself, if treated by this process, would become permanent buildings—all these, and many other applications of iron to the arts, would immensely gain by being submitted to this oxidizing action. I think I need hardly take up your time by enumerating other applications for the preservation of iron, for it appears to me that they would be commensurate with most of the uses to which iron is applied, save and except those where friction—such as that to which rails and iron wheels are exposed—would necessarily wear away the coating, as they wear away the material itself. I am happy to see a namesake of mine here present this evening, who will tell you that he is carrying out a process for the manufacture of peat into charcoal by the action of super-heated steam, and that he is enabled, by super-heated steam alone, to raise the temperature of his chambers to a red heat, quite sufficient to effect his carbonizing process. I will now call your attention to the specimens here before you, and to a description of the furnace which we employ, and I shall be most happy to explain, on being questioned, any parts of my process which may appear to be obscure, and to answer, if I can, any objections which you, gentlemen, in the interests of science, will feel it your duty to bring against it.

Parliamentary and Law Proceedings.

Personation at the Preliminary Examination.

At Bow Street on Saturday, the 17th inst., Andrew Ritchie Hunter, recently a clerk in the Savings' Bank department of the Post Office, was charged on a warrant, before Mr. Flowers, with aiding and abetting one John Thomas Falkner Colegrove, against whom a warrant was granted but who was not then apprehended, with procuring his registration under the Pharmacy Act. Mr. Straight appeared on behalf of the Pharmaceutical Society. It appeared that Colegrove having been doubtful as to his success in passing the Preliminary examination, the prisoner, a young man who had gained prizes and medals for having passed educational examinations, undertook to offer himself as J. T. F. Colegrove for the Preliminary examination of the Society which was to be held at Cambridge in October last. He wrote various letters in the name of Colegrove to the secretary of the Society respecting the forms of application, etc., necessary for the examination, and subsequently wrote, on the 2nd of October last, to the head of his office to excuse his attendance as he was ill, and took the opportunity to go to Cambridge, and underwent the examination by papers. He wrote again afterwards to know the result of his examination, and was informed that he had passed. The letters written in the name of "Colegrove" were identical in handwriting with that of the prisoner written to the head of his office, excusing his attendance on the ground of illness. The prisoner, on being apprehended by Detective Swanson, did not deny the charge. Mr. Straight said that the Pharmaceutical Society had acted upon the information contained in an anonymous letter received upon the subject.

Mr. Bremridge, the secretary of the Pharmaceutical Society, was examined shortly, and, after formal evidence from another witness, the prisoner was remanded.

On Monday last John Thomas Faulkner Colegrove was charged on a warrant before Mr. Vaughan with falsely procuring his registration under the Pharmacy Acts. Detective-Serjeant Andrews, Scotland Yard, deposed that after receiving the warrant for the apprehension of the prisoner he went to Liverpool, and from thence to Stamford, where he found him acting as manager to a Mr. Reeves, chemist. In answer to witness, the prisoner said he passed an examination in December last of the Pharmaceutical Society, but made no reply to a question put respecting the Preliminary examination at Cambridge. Witness took him to the station, and on the way to London the prisoner said, "I have regretted ever since I did it. It was very foolish of me. I passed my Minor examination so well, and also obtained two medals from the South London School of Pharmacy for proficiency, that I now feel I could have passed my Preliminary examination. My object was to save time." The prisoner also said that Hunter had passed for him. After some formal evidence the case was adjourned until Saturday (to-day), when Hunter will be again brought up. The question of bail was deferred.

Copper in Preserved Peas.

At Marlborough Street Police Court, on Monday, the adjourned summons against a number of foreign provision dealers in Soho for selling French preserved peas, alleged to be adulterated with copper was again before Mr. Knox. Mr. Philbrick, Q.C., attended, on behalf of the Strand Board of Works, to prosecute: Mr. Edward Lewis for the defence. Mr. Lewis asked the magistrate to give his decision in the case of Louis Barron, which had been fully argued on the last occasion, before proceeding with the other cases. It was understood that the matter stood over for the magistrate to consider his decision. Mr. Knox said the matter had been practically exhausted in Barron's case; but it would be the better course to take another case, as he understood many scientific persons were now prepared to give evidence. The evidence for and against Barron was so evenly balanced that he should adjourn that case *sine die*, and Mr. Lewis, if he thought fit, could apply for a *mandamus* to compel him to give a decision. Mr. Lewis was not desirous of taking such a course, alhtough he confessed to some disappointment in not having a decision as anticipated. It was then arranged that the summons against another defendant named Detmar should be taken. Formal proof having been given of the purchase of a tin of Brant's French preserved peas, Mr. Piesse, official analyst for the Union, stated that he had analysed the sample of peas submitted to him, and found 0·56 of a grain of copper. On the application of Mr. Lewis the certificate of the Government analyst at Somerset House was produced. From the certificate it appeared that the quantity of copper found in a similar sample of peas from the same tin was returned at 0·23. Mr. Lewis pointed out that in the case of Barron the Government analysis had found much less copper than Mr. Piesse had declared to be present. And in the present case there was a great disparity between the result of the analyses of the Government analyst and that of Mr. Piesse. The summons against another of the defendants, William Lingner, was taken. Mr. Philbrick said the proceedings were taken under the Sale of Food and Drugs Act, 1875, in respect of a tin of preserved peas sold by the defendants to the inspector appointed by the Board of Works, Strand Union, and which on being analysed were found to contain copper to the extent of ·088 of metallic copper, equal to 2¼ grains of sulphate of copper. The amount of copper might be small, but it was sufficient to be dangerous. Mr. F. Taylor, inspector to the Strand District Union, and Mr. Piesse, analyst to the Strand District Board of Works, gave evidence in support of the summons.

Dr. Conway Evans, M.D., medical officer of health, said he had been in practice for upwards of twenty years, during which time he had held several important appointments. He considered that the larger quantity of salt of copper spoken of in a 11d. tin of peas, if eaten daily or repeatedly, would be injurious to health and would produce chronic poisoning, but many persons might eat a quantity of these peas several times without apparently suffering any injurious effects, the period varying in accordance with difference of vigour, age, health, etc. Two or three doses might affect some persons and not others. From fourteen to fifteen grains of copper were sometimes given as an emetic, and sometimes in ague or chronic diarrhœa one-eighth to three grains were given as a tonic. It was a well known medical fact that in respect of some poisons—such, for instance, as mercury—certain persons were peculiarly susceptible to their influence, and it was possible that these peas containing copper, if swallowed by persons ignorant of their own susceptibilities, might, even in a single dose or a few doses, lead to injurious consequences. He believed copper was more fatal in a smaller dose than salt of lead. The heightening the colours of preserves with copper was once a common practice. Cases of poisoning by copper were formerly very common, but copper utensils in cooking had given place to tin and iron saucepans. Such cases were of rare occurrence. Pure metallic copper he believed to be harmless, but it was dangerous when in contact with other substances and when dissolved.

Mr. Philbrick here read the symptoms of chronic poisoning by copper; they were very slow and insidious, as described by Tardieu.

Dr. William Guy, M.B., F.R.C.P., and Vice-President of the Royal Society, said that cases of poisoning by copper had occurred in which the quantity swallowed must have been small. He had studied the question of poisons particularly. The fact of a trace of copper in the human body would not prove its existence in a poisonous form. He had made inquiries for Government into the effects of poisoning in certain trades. Palsy followed from poisoning by copper. Two cases had come under his knowledge of poisoning by green paper in a room. The poisoning, in his opinion, came from the copper, not the arsenic. Salts of copper he considered more poisonous than lead. The small quantity of copper contained in the peas in question from France might prove injurious, and slowly undermine health. On a nervous person copper was more likely to produce dangerous symptoms than on any one else. With regard to the presence of 3·6 of copper, if taken one-third at a time it would not affect a healthy person, and if repeated in small doses it would, in his opinion, be ultimately injurious to health. He considered that any article containing the amount of copper spoken to by Mr. Piesse should not be allowed to be sold for one moment. Sulphate of copper in its virulence ranked fourth in the class of poisons.

Dr. Charles Tidy, M.D., Professor of Chemistry and Medical Jurisprudence, and Medical Officer of Health for Islington, gave similar evidence. He had studied poisons, had experimented on fresh peas and pods, and found not even a trace of copper. If copper—that is, sulphate of copper—were constantly taken to the extent of the amount of copper found in the French peas it would be injurious to health.

Dr. Auguste Dupré, Ph.D., F.R.S., Lecturing Chemist at the Westminster Hospital, and President of the Society of Analysts of Great Britain stated that copper was present in traces only in animal and vegetable tissues. The quantity of copper found by Mr. Piesse was far beyond that quantity normally in any vegetable.

Dr. Grey said he considered the sale of an article containing such a quantity of copper as that found in the French peas ought not to be tolerated. Small doses of copper were more dangerous than large ones, as the latter would cause vomiting. The defendant said the peas were sent to him as quite natural peas.

Mr. Jenkins said the defendant had been convicted of a similar offence.

Mr. Knox said that, having been informed that the defendant has been before convicted for selling peas injurious to the public health, he saw nothing to cause him to mitigate the fine, which, he believed, went up to £50. He did not want to be oppressive, but the heads of the chemical and analytical kingdom had said there was not only a traceable quantity of copper in the peas, but a dangerous quantity.

Mr. Philbrick said the prosecution was instituted for the public benefit, and not with the view of punishment. The defendant said he did not sell three dozen tins in a year, and would discontinue the sale.

Mr. Knox, after cautioning the defendant and expressing a wish that publicity might be given to the fact that persons would not be permitted to bring to this country goods deleterious to the health of the inhabitants, and that in future real and substantial fines would be inflicted, fined the defendant the nominal fine of 1*s*. and £5 5*s*. costs.

Mr. Detmar having wished his case dealt with, he was similarly fined, and the other cases were adjourned.—*Times*.

Poisoning by Alcohol.

On Tuesday the 13th inst. Mr. Fullagar held an inquest at Eastbourne on the body of James Mason, 38, lodging-house keeper. The deceased went into the Sussex Hotel bar with two men, named Sims and French. There they met a man named Joshua Hatton, who treated them to a pint of raw whiskey. No sooner was it served than Mason drank off half of the liquor, the other men, Sims and French, drinking the remainder. Another was served, whereupon Hatton remarked, "I'll bet you two to one you don't tip that as you did the other." "I'll have you," said Mason, and he drank off more than he had previously done at a draught. He died the next morning, as the medical evidence showed, from alcoholic poisoning, and a verdict was returned accordingly. The jury said they wished to express very severe reprehension at the conduct of Hatton, and to suggest that the management of the bar of the hotel should be conducted more cautiously for the future as to the sale of spirits, but the Coroner did not record their representation.—*Times*.

Poisoning by Carbolic Acid.

The *British Medical Journal* mentions a case of death from poisoning by carbolic acid that has taken place at Liverpool. The deceased is said to have been an assistant in a druggist's shop, and to have drunk the carbolic acid in mistake, thinking it was a cough mixture.

Robbery at a Wholesale Druggist's.

At the Guildhall Police Court, on Friday, the 16th inst., John Okill, a carman, and William Osborne, a packer, both in the employ of Messrs. Battley and Watts, wholesale druggists, of 32, Lower Whitecross Street, were charged, on remand, with robbing their employers, and Dan Farrant, a linseed crusher, of Baron Street, Pentonville, and John Purser, a packer, living at 9, Manor Road, Bermondsey, were charged with receiving those goods well knowing them to have been stolen. On a previous occasion it was shown that the prisoners Okill and Osborne were suspected at the latter end of last year, and were watched by direction of Detective-Sergeant John Moss. They were then found to be in continual communication with each other. Detectives Henry Taylor and Frederick Downes watched them incessantly until the 8th inst., when Okill and Osborne were seen to lead the horse and cart out of the prosecutors' yard into Hanwell Street, Jewin Street, and, leaving them there, go into a public-house. They came out, and Okill drove the cart into Baron Street, got down, and went into Tarrant's warehouse. He came out, gave the carman money to get some beer, and as soon as he had gone into the public-house, took a parcel out of the cart and carried it into Tarrant's warehouse. Taylor and Downes followed him in, and saw him hand the parcel to Tarrant, who put it on a shelf. An officer searched the rooms of the house, 10, Baron Street, where he found 7lb. of Turkey rhubarb, 21lb. of tartaric acid, 21lb. of tartrate of soda, and other things, which were of a nature similar to those in the stock of Messrs. Battley and Watts. The prisoners were again remanded.

Review.

THE COMBINED NOTE-BOOK AND LECTURE NOTES, for the Use of Chemical Students. By THOMAS ELTOFT, F.C.S., etc. London, 1876. Simpkin, Marshall, and Co.

According to the author's preface, this small book was written with the view of assisting the chemical student in his home work, so that while knowledge may be acquired, it may be had without cramming. As might be expected, this attempt on the part of Mr. Eltoft has proved successful, for he has had considerable experience as a teacher of inorganic chemistry in colleges and schools. So far as we know, the book is quite novel in its construction.

The first eight chapters are taken up with information regarding the chemical elements, nomenclature and graphic formulæ, and observations on the formation of certain compounds, and the properties of gases. Then comes a note-book consisting of some eighty pages, so arranged that the student while following the lecturer may fill up with his notes spaces left opposite to certain headings. These headings relate to the occurrence, preparation and properties of bodies, together with the form of apparatus to be employed in studying, and the analytical tests which are characteristic of substances.

Following the note-book are eleven other chapters concerning the elements and their combinations, all reactions being represented by equations. Opposite the equations there are blank spaces for the student to fill up with the written meanings of the equations, and so forth.

Finally, there is given a series of tests for the principal acids.

Such a book as the one of which we are writing, may be made extremely useful in science classes where students have but few leisure hours to devote to their studies, for it must be admitted that the mere mechanical work incidental to study, is ordinarily very great, and in this instance much of this is obviated by the plan of the book.

In short as an adjunct to a text-book, it may certainly be recommended with safety, and Mr. Eltoft may be congratulated on having devised an ingenious means of helping students to obtain information.

BOOKS, PAMPHLETS, ETC., RECEIVED.

VISIONARY RHYMES, OR THE TUNINGS OF A YOUTHFUL HARP. By J. J. BROWN. Glasgow: J. Reid. 1876. From the Author.

LA VÉRITÉ SUR LE PRÉTENDU SILPHION DE LA CYRÉNAIQUE (*Silphium Cyrenaicum* du Dr. Laval); CE QU'IL EST; CE QU'IL N'EST PAS. Par F. HERINCQ. Deuxième édition. Paris: Lauwereyns. 1876. From Dr. Méhu.

AIDS TO BOTANY. By C. E. ARMAND SEMPLE, B.A., etc. London: Baillière, Tindall and Cox. 1877. From the Publishers.

Notes and Queries.

[537.] DRY ROT.—Prevention: Convert the surface of the dry timber into coal either by heat or sulphuric acid. Destruction: Diluted sulphuric acid, solution of sulphate of iron (ten per cent.), acidum pyrolignosum.

[538.] TOOTH STOPPING.—Non-expensive metallic tooth stopping. Amalgam of mercury and copper. Take one part of sulphate of mercury, one part of copper in fine powder, rub it well together with a little warm water; when the amalgam is formed wash well and remove the surplus of the mercury by pressing it through chamois. Expensive metallic tooth stopping and much preferable: Take pure gold, pure gelatine, one part of each, pure silver, two parts, melt, and when refrigerated reduce to powder by means of a file; wash well, and dry. In the moment of using it, add sufficient mercury to form a plastic mass.

[539.] ESSENCE OF MUSK.—Tinctura moschi e vesicis:—

R. Vesicæ moschi concisæ, partem unam.
Spiritus diluti,
Aquæ destillatæ, ad partes viginti quinque.
Digestione fiat tinctura.

Should be used only in perfumery.

H. W. L.

[540.] PRESERVATION OF MUSHROOMS.—Does any reader know of a good method of preserving mushrooms for scientific purposes? Plaster of paris answers well only for agarics.

H. W. LANGBECK.

PUMPKIN SEEDS.—A recent investigation of pumpkin seeds, which are largely used in Russia as a vermifuge, has enabled Kopylon to affirm (*Pharm. Zeitsch. f. Russland*, xv., 513) that they do not contain an alkaloid. Neither has he been able to confirm the presence of the crystalline glucoside reported by Dorner and Wokkowitsch. The oil obtained from the seeds by pressure was found to consist of glycerides of palmitic, myristic and oleic acids. Oil extracted by ether contained also free fatty acids.

A GUM QUERY.—Mr. Parker will find a description of the gum he speaks of (see p. 687) in Hanbury's and Flückiger's 'Pharmacographia,' p. 210, note 3. To my knowledge it has been in the market for at least the last eighteen months, and there seems no reason to doubt that it is a genuine gum arabic.

CHARLES EKIN.

"CARBOLATE OF IODINE" (Dr. Percy Boulton's formula, from *The Pharmacist*.)—

Tinct. Iodinii Comp.	fl.ʒ j.
Acid. Carbolici	♏ vj.
Glycerinæ	fl.ʒ j.
Aquæ	fl.ʒ v.

M.

The solution soon loses its iodine colour, becoming clear and colourless. It is used for inhalation.

The Milk of Sulphur Question.

Sir,—As the purely commercial and common-sense aspect of the milk of sulphur question seems in danger of being overlooked amid the amount of historical and scientific information its discussion has called forth, let us suppose an analogous case in a different trade.

Say that one of those virtuous individuals who are morbidly sensitive about having things called by their right names, orders from his tailor a pair of doeskin trousers. Finding that he gets cloth, not skin, he prosecutes the maker for fraud, as the garment is not of the nature and quality demanded. The defendant denies fraud, pleads trade usage and common custom, alleging that garments made of real skin, although not unknown, are seldom wanted, and that he could not reasonably be expected to know that his customer wanted something different from the material usually called doeskin, no special intimation to that effect having been given.

Plaintiff produces in court works on natural history and dictionaries to show that doeskin means or ought to mean the skin of an animal, and maintains that had the real skin been the cheaper of the two, it would have been supplied.

Can there be any doubt that in such a case a magistrate would at once admit the plea of trade usage and common custom, and dismiss the action, telling plaintiff that if he wanted real doeskin, he should have taken care to say so?

Plaintiff would also probably receive a hint from defendant, that if he did not apologize and moderate his expressions about fraud, a civil action for damages might be found necessary to teach him proper respect for conventional terms. Substitute for "doeskin" in the above, the words "chamois skins," and the analogy will be equally exact.

Now, the Runcorn milk of sulphur case differs from the supposed one only in the greater strength of the defendant's position, for he can plead the authority of the London Pharmacopœia for his preparation, besides the trade usage and common custom of more than a century and a half. An authorized preparation may be faulty, in the opinion of some, but it cannot be called adulterated, when the presence of certain ingredients is a necessary result of the process prescribed.

If our Runcorn friend maintains firmly that milk of sulphur was asked for and supplied, and that if the purchaser had wanted pure precipitated sulphur he should have said so, a magistrate will have some difficulty in finding a reason for convicting.

Indeed, if any wrong has been done, the druggist is the person aggrieved, as he is made the victim of something very like a fraud, when advantage is taken of the double meaning of a word to prosecute him for selling adulterated medicines.

As to the relative therapeutic value of the two preparations known as milk of sulphur, that has really nothing to do with the point at issue.

The continued popular demand, however, for the old lac sulphuris extending over many generations, coupled with the fact that where the so-called pure has been offered it has been generally rejected, and that persistent attempts to sell only the pure precipitate have resulted in diminution or entire loss of trade in the article, seem to indicate that the common milk possesses some special advantages over the so-called pure.

As a case in point, to show that popular tradition is sometimes right when scientific authority is wrong, let us remember the strong condemnation passed by Dr. Paris in his 'Pharmacologia' upon Friar's balsam. He states, "that with respect to the use of this preparation as a styptic, the public have fallen into a serious error; fresh wounds it must necessarily injure," etc. This severe sentence must certainly have prevented many medical practitioners from using it: indeed its employment has been long regarded as decidedly unprofessional. Now, however, working their devious way through carbolic and salicylic, to benzoic acid, the profession are beginning to recognize the fact that the despised Friar's balsam combines the antiseptic and air-and-germ-excluding advantages which they have been searching to attain by other and less efficient means.

In conclusion, let me express a hope that common sense may be allowed to play its part in our trade as in others, and that our Yorkshire and Lancashire brethren may continue to sell their popular medicine labelled by its proper name, milk of sulphur, without any puzzling intimation that it is not something else, and relegate giving the information that it contains calcium sulphate to the time when it shall be considered proper to label the familiar cream of tartar as "acid potassium tartrate," or "hydropotassic tartrate," or when carbonate of soda shall be commonly asked for as the "disodic carbonate."

Alex. Kinninmont.

Glasgow.

Sir,—Surely it is high time that the discussion upon milk of sulphur was brought to an end.

After Dr. Redwood's exhaustive letter, I cannot understand how there can be two opinions upon the legal bearing of the case.

In 1721 an article containing sulphur and sulphate of lime was introduced into the Pharmacopœia under the name of lac sulphuris. In 1746 an altered mode of preparation was ordered, and to the article prepared under the new process was given the name of sulph. præcip., the chemical composition of the two substances remained more or less the same.

In 1789 the mode of preparing sulph. præcip. was altered, and an altogether different product was the result; this contained no sulphate of lime, but consisted of pure sulphur, and since that time sulph. præcip. has remained of the same chemical composition, and has been recognized as such, both by chemists and medical practitioners, and has been quoted as a distinct article in wholesale druggists' price lists.

Since previous to 1746 no article has been officially recognized by the name of lac sulphuris, so that instead of remaining an officinal preparation, the preparation of 1721 containing sulphur and sulphate of lime became an article of commerce, and is recognized as such at the present time, and by many is highly appreciated, in fact much more so than its more aristocratic descendant sulph. præcip.

No preparation not identical in chemical composition with that of 1721 has a right to usurp the title of lac sulphuris, and surely 150 years' possession ought to establish a right to the title.

Now, Sir, the difference of opinion upon the case seems to arise from the fact that some of your correspondents aim at acting up to a high standard of pharmaceutical morality (a very laudable aim), and owing to the favourable circumstances under which they are placed, they have no difficulty in carrying out their own exalted views, and consequently scorn to sell a contaminated article (during an experience of twenty years I cannot remember ever having sold the old-fashioned lac sulphuris); these should remember that there are others of their brethren who are less favoured, and have to meet the commercial requirements of an altogether different class of patrons, many of whom when they ask for their pennyworth of milk of sulphur would express dissatisfaction at being supplied with a new fashioned article, and only those with a poor class of customers know how obstinate they are in their ideas.

In conclusion, milk of sulphur is an article identical in chemical composition with the preparation of 1721; the advanced pharmacist may supply sulph. præcip. if he pleases, but to prosecute a chemist for strictly supplying the article asked for simply because it is not an officinal preparation, is an act of monstrous oppression.

Jas. Swenden.

Darlington.

Sir,—So much has been said and written of late respecting this article, that the following fact may be of interest to your readers generally. Some years ago, a military officer of high rank called upon me with a prescription for an electuary, composed of precipitated sulphur and confection of senna, and which he said had recently been dispensed in a distant part of the country, but that very much to his surprise and annoyance, it had quite a different effect to that intended. This in my opinion was caused by the use of the impure milk of sulphur, containing as it does 50 per cent. of sulphate of lime, for when the prescription was made up with the pure precipitated sulphur, the effect was, as desired, laxative. I may add my testimony also, as a pharmaceutical chemist of thirty years' standing, that I never found the impure article inquired for by my customers.

A PUBLIC ANALYST.

North Wales, Feb. 20.

Sir,—To my mind it is really amusing to see the manner by which Mr. Ellinor seeks to establish a complete identity between what he himself in effect so tacitly admits as two distinct articles.

The reasoning process which he employs to arrive at this may be likened to the idea that, under certain circumstances, truth and falsehood are alike; and that that circumstance in respect of the two articles, lac sulph. and sulph. præcip., consists in the indiscriminate use of either name to express both, or, in other words, something after the fashion of expressing things in terms such as contained in the following sentence:—"That black is white, and blue no colour at all."

I think by the mere rule of priority, without mentioning others, that no preparation of sulphur has so clear a title to the name lac sulph. as the preparation of the 1721 Pharmacopœia, and as that name has nothing at all in it, as representing it chemically, more than of an ideal character, I can therefore see no harm why it should not be retained and solely applied to the article containing sulphate of lime as well as in contradistinction to the present uncontaminated sulph. præcip.—leaving full liberty of action to all chemists to supply that which they in their consciences think the best, medicinally.

As to the name sulph. præcip., which it appears the compilers claimed in a subsequent Pharmacopœia to that of 1721, for a preparation which, though obtained by a somewhat altered process to that of that date, but which nevertheless yielded a result identically the same; of that and the appropriateness of the name applied I will leave for Mr. Ellinor to judge and to speak of how far he thinks such a name does constitutionally represent the article in question; and also as to whether he would not think that such a preparation as that of the present Pharmacopœia a far better claimant for the name than one which he himself must know, by virtue of the very process ordered to be employed, to yield the contaminated product.

I really think then that it is a great pity to see that there should be so much conservatism about this name, lac sulph., especially with those, like Mr. Ellinor, who, while advocating with such apparent consistency the necessity of calling things by their proper names, should, as it appears to me, retain in this case, and that for no other purpose than that of trade, such fancy, meaningless and unscientific name as lac sulph. to express an article which cannot be better and more truthfully represented under any other name than that of precipitated sulphur.

Now, if there was any rule by which we could classify chemicals like plants, then I should say, speaking for myself personally, as regards this preparation, lac sulph., about which so much difference of opinion exists, that it would in such case most certainly take its place under the head "sulphur," merely as a species or variety, and as such must, like all other nearly related things, have a name assigned to it, to wit, lac sulph. or some other; but distinguish we must whereinsoever they differ as regards the process and the legitimate result yielded; and therefore as regards the processes of the 1721 and 1746 Pharmacopœias on the one hand, and the process of the present Pharmacopœia on the other, I cannot for myself recognize any other identity between them than this, viz., that of their possessing some, still not all the characters in common of the pure precipitated sulphur, and for this reason ought to be different in name as they are in kind.

A. P. S.

February 19, 1877.

SANTONIN.

Sir,—Seeing the case of poisoning by santonin reported in your Journal of last week, I beg to call attention to the following paragraph, taken from *The Druggists' Circular* (New York) of this month:—

"*Dangers from Santonin.*

"In using santonin, it is well to bear in mind that comparatively small doses have produced convulsions of a somewhat grave character. A German paper lately reported a case in which poisonous effects were produced in a child two years old by the ingestion of so small a dose as a grain and a half. Convulsions commenced in the face and extended to the extremities, while the respiratory action was greatly impeded. Under warm baths, enemata and artificial respiration the patient recovered. The physician in charge of the case then instituted a series of experiments on the lower animals, and found that chloral and ether inhalations controlled the convulsions produced by santonin. He naturally argues that the same treatment should be pursued in the human subject when a poisonous dose is taken."

In this case the symptoms described bear a very close resemblance to those of strychnia poisoning, and the antidotes found to be useful in cases of overdoses of santonin are similar to those generally recommended for strychnia. As no chemical analysis, proving the presence of strychnia, appears to have been made in the Manchester case, is it not possible that this may be a true case of poisoning by santonin, and not by strychnia, as supposed?

368, *Clapham Road.* A. RIVERS WILLSON.

[*** The evidence given was distinctly to the effect that the santonin was mixed with crystals of strychnine.—ED. PHARM. JOURN.]

F.C.—Several recipes for this preparation have already been given. See vol. vi., p. 598.

C.J.H.—Questions such as you have sent, involving in an answer the recommendation of a particular firm, are inadmissible to these columns.

T. Martin.—The Pharmacy Act, 1868, does not apply to Ireland.

W. L. Yates.—It would be unsafe to do so without the permission of the Inland Revenue Commissioners.

J. H. Talbot.—The only persons who can authoritatively answer your question are the Inland Revenue Commissioners.

C. F. Jarvis.—We believe so. Apply to the Secretary of the Apothecaries' Company.

"*Picroglycion.*"—We think in such a case a pharmacist is justified in acting according to his discretion, and is not bound to give his reasons to his customer.

"*Beta.*"—(1.) *Pharm. Journ.* [3], vol. ii., pp. 21 and 41. (2.) Semolina is the large hard grains of wheat flour, retained in the bolting machine after the finer flour has passed through. Manna Krout is a granular preparation of wheat, deprived of bran.

J. Cock.—A series of articles on the subject are in course of publication in the *Echo*, and could probably be obtained by applying at the office, Catherine Street, W.C.

H. de Styrap.—We cannot say. We doubt whether such a substance is imported as an article of commerce.

R. Stinton.—The quantity is usually about 60 per cent.

"*Syrupus.*"—(1) *Tortula muralis, β. rupestris*; (2) *Bryum capillare*; (3) *Tortula convoluta*; (4) Send a better specimen; (5 and 6) *Hypnum serpens*; (7) *Hypnum velutinum*; (8) *Hypnum confertum.* There is no book such as you require at present.

J. B.—The decomposition cannot be prevented. Dilute before mixing the ingredients.

J. Wingrove.—When "Liq. Arsenic." is ordered Liquor Arsenicalis, B.P., should undoubtedly be dispensed, not Liquor Arsenici Hydrochloricus.

"*Beta.*"—The answer to your question is to be found out by experiment, which we would recommend you to undertake for yourself.

Felix Stevens.—We understand it is expected that the Year-Book of Pharmacy will be published at the end of the month.

COMMUNICATIONS, LETTERS, etc., have been received from Mr. Heynes, Mr. Wingrave, Mr. Munday, Mr. R. Williams, Mr. S. Taylor, Gnol, G. W. G., W. H. S., A. P. S., F. J. K.

CHRYSOPHANIC ACID AND ITS SOURCES.

BY W. LAUDER LINDSAY, M.D., F.L.S., F.R.S.E.

If it be of any consequence to procure this acid in quantity for use in the treatment of skin or other diseases, there is a much more plentiful and much cheaper source of supply than any of those mentioned by recent writers in the *British Medical Journal*. No doubt it occurs in medicinal rhubarb, Goa powder, and senna leaves, as various writers in the said journal point out. These articles, however, from which it is produced by chemical means, are of foreign growth, are scarce in the drug market, and are, therefore, more or less costly. On the other hand, the acid is to be found in, and may be extracted with ease, I have every reason to believe, from, an indigenous plant that occurs literally everywhere, the cost of which is simply that of collecting and cleaning it. I allude to the common yellow wall *lichen*—the *Physcia parietina*, L., of botanists. To chrysophanic acid the said lichen owes its beautiful colour, as do certain other lichens, such as *Placodium elegans*, Link, and *Chlorea vulpina*, L. So abundant is it in the first-named lichen, which has been its usual source of supply to chemists, and so long has it been known to chemists as one of the products of that common lichen, that it has been more familiar to them as Parietinic, than as chrysophanic acid—synonyms being Parietin and parietic acid—all so named from the specific designation of the lichen, *parietina*, wall-growing. The very abundance of *Physcia parietina*, on walls, on rocks and stones of all kinds, on house roofs, gate posts, fences, trees, and shrubs in all the three kingdoms, and all the lowland parts of them, and the care and cheapness with which it may be collected, may, however, operate to its disadvantage. For about a quarter of a century I have been pressing on the attention alike of chemists, pharmaceutists, and physicians, as eminently deserving their attention, *the medicinal products derivable from lichens*, and I have done so in vain. The same kind of neglect has been shown as regards the products of the fungi and algæ, as well as of our highest forms of vegetation that are *indigenous*, and apparently because they are so. Indubitably the proverb that "Far away fowls have fair feathers" is as true of fashions in medicine as of fashions of other kinds. Products appear to be valued because they are *foreign*, and the more foreign and rarer the better; while our own plentiful, cheap, otherwise worthless, or at least non-utilized plants, phænogamic as well as cryptogamic, are neglected, nay, despised. Pliny reproved *his* countrymen for neglecting what was near and pursuing what was distant.—"*Proximorum incuriosi, longinqua sectamur.*" But the reproach is quite as applicable to ourselves, to our day and generation, as to the countrymen and contemporaries of Pliny. In short,

> "'Tis *ever*: What's within our ken,
> Owl-like, we blink at, and direct our search
> To farthest Inde in quest of novelties,
> Whilst here, *at home*, upon our very threshold,
> Ten thousand objects hurtle into view,
> Of interest wonderful."

Now the fact is that our own indigenous lichens abound in products that have been, or might be, used in medicine: some of them as substitutes for, or rivals to, such substances as quinine and salicin. Not only do they give us starches and mucilages, alcohols, and other products, which, however serviceable to man, are non-medicinal, or may be so considered; but lichens yield also—to the ingenuity of the chemist—acid or other principles that are tonic, febrifuge, antiperiodic, astringent, anthelmintic, or purgative, just as they furnish also a series of splendid dyes that continue to stand their ground against the aniline colours of recent introduction. In connection with these valuable dyes, and also with their use as food for man or other animals, lichens have been made the subject of repeated investigation by chemists, chiefly continental. In this country, Dr. Stenhouse, of London, and Dr. Schunck, of Manchester, both Fellows of the Royal Society, have distinguished themselves by their researches on lichen products of the *tinctorial* class. Little, however, has been done in reference to the use of lichen products in *medicine*,* though not a few monographs of a general kind have been published, chiefly in Germany, Sweden, or other continental countries. As much, perhaps, is known of parietinic, now described as chrysophanic, acid as of any other lichen product that has been used, or that has been proposed for use, in medicine. Its application to the treatment of skin diseases would appear to be comparatively recent, but it is far from being the most important application that may be made of it. Many years ago it was brought forward as a rival of quinine; and it has yet to be decided, indeed, what are its curative virtues, if any, whether externally applied or internally administered.

Much of what we know of the nature and properties of parietinic acid is unquestionably due to its brilliance as a colouring matter. Our present knowledge amounts mainly to the following:

The name "chrysophanic acid" was given it by Rochleder and Heldt, the German chemists who first properly studied its composition. In so far, however, as it is better known generally as a product of Russian and East Indian rhubarb, the acid in question has also been denominated *Rhéin*, or *Rheic acid*, and *Rhabarbarin*. There is a substance known as *Rheumin* and *Rhubarbaric acid*, as well as *Parmelia yellow*, which may or may not be identical with chrysophanic acid. For *Physcia parietina* is described as containing *two* yellow colouring matters, one of which is non-crystallizable (W.).

The composition of chrysophanic acid, according to different chemists, is—

$C_{10}H_8O_3$ (Rochleder and Heldt).
$C_{10}H_8O_6$ (Pereira).
$\left.\begin{matrix} C_{10}H_4O_3 \\ C_{40}H_{16}O_{12} \end{matrix}\right\}$ (Gregory).

Its general characters are these: It occurs in golden-yellow crystals (Gregory), but Pereira describes the pure acid as *granular* and not crystalline. With solution of ammonia or potash it yields a splendid red colour. Its salts, while red in solution, are blue or violet when dry (Gregory). If the potash solution be evaporated to dryness, the red changes to violet and blue. Chrysophanic acid, therefore, is, from one point of view, a *yellow* colouring matter,

* I introduced a short section on the "*Medicinal Substances*" they yield, in a paper on "The Economical Applications of British Lichens," published in the *Phytologist*, vol. i., new series, 1856, p. 187.

from which is derived a secondary *red* dye, known as Parmelia red (W.)

Among the synonyms of chrysophanic acid, I find "usnic acid," just as "parietine" is given as a synonym of Usnic acid. In both cases there is probably mistake or confusion—as usnic acid, which was also examined and described by Rochleder and Heldt, occurs in a different series of lichens. It may, however, occur sometimes in the same lichens with chrysophanic acid. So far as *colorific* properties are concerned, its character is similar to that of chrysophanic acid. The latter acid is also liable to be confounded with Vulpinic acid, which occurs in two of the same lichens that contain chrysophanic acid—*Chlorea vulpina*, and *Physcia parietina*: in which case it is at present impossible to determine the part played by vulpinic acid in the vivid coloration of the lichen thallus.

Those who desire information concerning parietinic acid in particular, or the medicinal products of the lichens in general, may consult the following works, some of which give full references to monographs on these subjects, mostly published in Germany.

I. Lindsay: 'Popular History of British Lichens,' 1856; pp. 80—4, 91—93, 125—6, 129, 131, 137, 142, 145, 148, 152—3, 155—9, 164—5, 168, 175, 183, 200, 208—210, 229, 267, 269, 273, 297, 320.

COMPARATIVE EXAMINATION OF THE MORE IMPORTANT COMMERCIAL VARIETIES OF GALBANUM AND AMMONIACUM GUMS.*

II. AMMONIACUM.

BY EDWARD HIRSCHSOHN.

(*Continued from page* 614.)

5. *Chemical Composition.*—The first chemical analyses of Persian ammoniacum were made by Cartheuser, Neumann and Löseke. Braconnot, Buchholz, Calmeyer and Hagen also examined this gum resin. They found its composition to be as follows:—

	Braconnot.	Buchholz	Calmeyer	Hagen.
Resin	70·0	72·0	53·0	68·6
Gum	18·4	22·4	37·2	19·3
Gum-like substance, insoluble in water and alcohol	4·4	—	—	—
Glutinous Matter	—	1·6	—	5·4
Extractive	—	—	—	1·6
Water	6·0	—	—	—
Loss	1·2	—	—	—
Volatile Oil and Loss	—	4·0	—	—
Volatile Oil	—	—	—	2·8
Woody Fibre and Sand	—	—	7·8	2·3

* From a memoir for which the gold "Suworow" medal has been awarded by the Medical Faculty of the University of Dorpat. (*Pharmaceutische Zeitschrift für Russland*, April 15, 1875, p. 225).

All authors agree that the resin is reddish. Berzelius states that it melts at 54° C.; Vigier at 45° C. It smells like the gum resin and is tasteless. An alcoholic solution of the resin gives no precipitate with acetate of copper (Vigier). It is easily soluble in alcohol and in fixed and volatile oils, but only partially in ether. Sulphuric acid also dissolves it, from which solution it is again precipitated by water. With caustic alkalies it forms a turbid and very bitter solution. Johnston found its composition to be $C_{20}H_{24}O_3$. By fusion of the resin with potassium hydrate Hlasiwetz and Barth obtained resorcin.

The gum has always been described as similar to gum arabic.

The volatile oil is colourless, lighter than water, and has a strong ethereal odour and bitter taste. From the gum resin Martius obtained 1·1 per cent., Hagen 3·84 per cent., and Vigier 1·8 per cent. of its weight of an oil that was considered to be sulphuretted, because it had the property of blackening silver. Moss, however, in examining Persian ammoniacum for sulphur obtained negative results. By treatment of the gum resin with solution of chloride of lime it is coloured orange yellow.

African ammoniacum has been examined by Moss, and the results were published in this Journal in 1873.* He found the composition to be—

Resin	67·760
Gum	9·014
Water and volatile oil	4·290
Bassorin and insoluble matter.	18·850
	99·914

According to Moss the resin is reddish brown shining, and so soft as to receive readily and retain for some time the impression of the finger nail. It shows a wavy fracture, and possesses to a small degree the peculiar odour of the crude drug, but no taste. It melts at 38·5° C., dissolves readily, acquiring a red colour, in solutions of fixed alkalies and in oil of vitriol, especially with a gentle heat. The gum was similar to that from Persian ammoniacum. The gum resin upon incineration gave 13·47 per cent. of ash, consisting of calcuim carbonate, sand, iron, oxide, alumina, and a trace of calcium sulphate.

6. *Description of the sorts examined by the Author.*

A. Persian Ammoniacum.

1. Ammoniacum in granis from the collection in the Pharmaceutical Institute, Dorpat. Variously formed grains, attaining 8 centimetres in length, brittle, reddish yellow, opaque, with a waxy appearance. Fracture vitreous. Smelt faintly of ammoniacum.

2. Ammoniacum in granis. The same colour, but rather lighter, and similar to the preceding.

3. Ammoniacum in granis, from Hamburg, 1873. Variously formed pieces, attaining 2 centimetres in length; colour as No. 2, fracture vitreous; not brittle, but could be cut with a knife.

4. Ammoniacum in granis, from the Lucæ collection. Small granules, the size of peas; of a gamboge yellow colour; fracture waxy yellow, mixed with white.

5. Ammoniacum in lacrymis, from the same. Tears the size of lentils, of a gamboge-yellow colour; fracture the same colour, brittle; smell very weak; mixed with fruit and pieces of stalk.

6. Ammoniacum in globulis, from the same. Similar to No. 3, but somewhat darker.

* Vol. iii., p. 742.

7. Ammoniacum in globulis, obtained through Dr. Méhu of Paris, 1874. Like No. 3.

8. Ammoniacum in massis, from Hamburg, 1874. Irregularly formed masses of various sized tears agglutinated together; colour light reddish yellow; fracture milk white, vitreous; mixed with variously coloured small stones.

9. Ammoniacum in massis, from the Lucæ collection. Reddish-green masses of agglutinated granules, the contour of which gave to the fracture a marbled appearance.

10. Ammoniacum in massis, from the same. Similar to the preceding; colour from reddish yellow to dirty brown.

11. Ammoniacum in massis, from the same. Composed of umbelliferous fruits, small angular pieces of brittle, yellowish-red resin, small stones, and pieces of stalk.

12. Ammoniacum in massis, from a Dorpat pharmacy. Like No. 9.

13. Ammoniacum in globulis, from a Dorpat pharmacy. Variously formed pieces, some as large as an apple; part like No. 3, and part consisting of angular moderately soft masses, mixed with small stones and fragments of stalk, of a uniform dirty brown colour, and presenting a wax-like appearance on the surface of the fracture.

14. Ammoniacum in massis, obtained from Apothecary Osse, in Astrachan, and purchased by him from Persian traders. Various sized masses, containing throughout large fragments of stalk; here and there marked with white veins, and black spots sometimes of earth.

15. Ammoniacum in massis, from Apothecary Osse, Astrachan. Like No. 14, but wanting in the milk white veins, whilst the earthy portions often amounted to half of the mass.

16. Ammoniacum in massis, from the Dorpat collection. Principally angular masses, containing thin stalk fragments, interspersed with milk-white particles; also agglutinated or single granules, almost orange coloured, with a milk-white fracture.

17. Ammoniacum depuratum, from the Dorpat collection. Honey-yellow, agglutinating, easily triturated mass, having a weak smell.

18. Ammoniacum in massis, obtained through Dr. Méhu, from Paris, 1874. Like No. 9.

19. Ammoniacum in massis, from the same. Angular, tolerably hard, light brown pieces, frequently shining on one side, interpersed with a few very thin stalk fragments, and very many small milk-white angular particles, giving to it the appearance of porphyry.

B. African Ammoniacum.

20. Obtained from Mr. D. Hanbury. Large, compact, heavy masses, formed of agglutinated tears of a soft gum resin; the tears are dull white or yellow, occasionally brown to blackish, contaminated with much earth and vegetable matter. Smell peculiar, almost recalling baked apple and lavender.

7. *Behaviour with Reagents.*—Upon adding a drop or two of concentrated sulphuric acid to a small fragment previously moistened with alcohol, the Persian ammoniacum gave a yellow-brown and the African a red-brown solution. Upon the addition of water the Persian solutions threw down a flesh-coloured precipitate, and the African a dirty violet precipitate. Hydrochloric acid used in the same way gave no particular reaction (differing from galbanum and sagapenum). Chloride of lime solution coloured all the samples (except No. 20) citron yellow, which colour passed gradually into a more or less intense orange (distinguishing from galbanum).

8. *Distillation with Water.*—By the distillation of 300 grams of No. 13 with water, in the manner described under "Galbanum," no oil was obtained; the distillate smelt strongly of ammoniacum and was faintly acid, but gave no reaction worth mentioning.

9. *Mineral Constituents.*—The gum resin (as under "Galbanum") incinerated gave the following results:—

No.	Description of Ammoniacum.	Per cent. of Ash.
1.	In granis, from Dorpat Institute.........	2·29
2.	„ „ „ „ „	2·59
3.	„ „ „ Hamburg, 1873	2·02
8.	„ massis, from Hamburg..................	14·30
12.	„ „ „ Dorpat pharmacy	2·98
14.	„ „ „ Astrachan	7·94
15.	„ „ „ „	16·88
17.	„ „ „ depuratum	3·51

The composition of the ash was similar to that from galbanum, and showed by its percentage that the collection had not always been carefully made, or that there had been probably an intentional mixture with sand.

10. *Moisture.*—An estimation of the moisture, by loss, gave the figures in the following table.

No.	Description.	Moisture. Per cent.	Per cent. soluble in Petroleum.	Ether.	Alcohol.	Water.	Residue. Per cent.

11. *Treatment with Petroleum Spirit.*—Treated with petroleum as described under "Galbanum," residues were obtained, the percentage quantities of which are shown in the table. All the liquids, as also the residues,—with the exception of No. 20, which was slightly yellow,—were colourless, and had a decided smell of ammoniacum. The almost perfect volatilization of the residues when heated to 120° C. indicated that they were derived from essential oils. The residues from Nos. 2, 6 and 7 amounted to from 0·3 to 0·8 of the gross weight of the drugs; the residues did not redissolve in petroleum spirit. Chloral and chloral hydrate gave with the residues from Persian ammoniacum a faint green colour and with that from African ammoniacum a light brown.

The testing of the petroleum spirit residues for sulphur, by deflagration with pure saltpetre, always gave negative results.

Treatment with Ether.—The ethereal solutions gave upon evaporation residues of resin, the percentage weight of which is shown in the table. The resin was yellow to dark brown and brittle, with the exception of No. 20, which was softened by the heat of the hand. The melting point for Nos. 1 to 7 was estimated at 45° C.; for Nos. 10, 11, 12, 14 and

15 at 42°; for Nos. 7, 8 and 17 at 45°; for No. 19 at 50°; and No. 20 at 35°.

Concentrated sulphuric acid dissolved the resin with a yellow colour; alcohol (95°), chloroform, glacial acetic acid and amylic alcohol dissolved it readily; carbon bisulphide and benzin only partially; solution of ammonia took up the greater part (differing from galbanum) and coloured the residue yellow. Potash and soda solutions also dissolved it, especially when heated, forming then an almost blood-red solution.

The resins gave no reaction for sulphur when deflagrated with saltpetre. The alcoholic solutions of the resins gave precipitates with sugar of lead and acetate of copper. Silver nitrate was only slightly reduced after thirty-six hours. When boiled with water the resins coloured it yellow and gave it an acid reaction, with the exception of No. 20, with which the water remained colourless. Neither by dry distillation nor by treatment with hydrochloric acid could umbelliferon be obtained from the Persian resin (differing from galbanum); but the African resin gave a large quantity of umbelliferon both by dry distillation and by treatment with hydrochloric acid.

The yellowish solutions from the Persian resins were coloured red violet by perchloride of iron and orange yellow by solution of chloride of lime; sugar of lead, while decolorizing the solutions, gave a yellowish precipitate. The author found by experiments with solutions of phloridzin and phloretin that a body similar to them had been removed from the resin by the water. African ammoniacum did not contain this body, but yielded umbelliferon instead. The alkaline (soda) solutions of the resins, when decomposed with chloride of barium, behaved like those of galbanum.

13. *Treatment with Alcohol.*—The experiments were made as described under "Galbanum," and gave the results stated in the table. The alcoholic residues were coloured like those from galbanum, but were not perfectly soluble in cold alcohol though soluble in warm. Water dissolved the larger proportion, the more or less coloured solutions behaving like those from galbanum; perchloride of iron however gave with them, No. 20 excepted, a wine-red mixture, from which a red body was deposited after some time. Fehling's solution was reduced and yeast liberated carbonic acid. The residues therefore contained a kind of sugar.

14. *Treatment with Water* gave the results shown in the table. These residues behaved towards reagents and polarized light like those obtained from galbanum. In this case also water extracted an inactive mucus and a body resembling dextrin.

15. *Insoluble Residue.*—The residues left undissolved after these successive treatments are given in the table. In Nos. 1 to 4, 6, 7, 10, 12 and 18 the insoluble residues consisted only of a substance analogous to bassorin; in the other sorts it varied with the nature of the impurities. Starch could not in any case be detected. In Nos. 1 to 4, 6, 7 and 18 *débris* of cells was clearly seen under the microscope.

All the samples of Persian ammoniacum in massis contained more or less fragments of stalks and fruit, but the grains contained fruit only. No root fragments were found in any sort.

(To be continued.)

ELIXIR OF MONOBROMATED CAMPHOR.

BY I. MUNDAY.

Some time ago, at the request of Dr. E. Warren Bey, I tried several experiments to obtain an elixir of the above, and succeeded in making one containing one per cent. of monobromated camphor, being double the strength of the formula published in *L'Union Pharmaceutique*, an abstract of which was given in the *Pharmaceutical Journal* of the 17th February.

Instead of sugar I use glycerine, which I find suspends it much better when mixed with water; in fact, in certain proportions the mixture is perfectly clear, whilst with sugar there is a film formed on the glass. The formula I use is as follows, which contains one per cent.

Monobromated Camphor . .	30 centigrams
Alcohol at 90°.	12 grams
Eau de fl. de Oranger . . .	8 „
Glycerine	10 „

Mix the alcohol, glycerine and orange flower water together and dissolve the monobromated camphor by aid of a gentle heat.

14, *Rue de la Paix, Paris.*

NOTE ON THE ADMINISTRATION OF PHOSPHORUS.*

BY EDWARD R. SQUIBB, M.D.

(*Concluded from page* 696.)

It is so very difficult to prevent phosphorus from oxidation when in contact with substances containing oxygen, and when in contact with substances which contain no oxygen so difficult to prevent its combination with other elements which impair or destroy its activity, that it is not easy to understand how it can ever reach the circulating fluids of the body as free or uncombined phosphorus. Yet that it does so seems now pretty well established; and if it does so, a solution under the protective agency of a combination with oil-globules which, by emulsion in the intestinal tract, pass into the chyle, is the most rational. Whether its ultimate effect in the tissues be as phosphorus, or as phosphoric acid, must still be very doubtful, when it is remembered that before reaching the tissues it is aerated in the lungs. That "phosphorus can never be effectively employed but in its free and most active state" (Thompson, p. 9) is abundantly disproved by the experience of this country, and especially by the systematic observations in large hospitals for the insane (see especially a paper on "The Physiological Action and Therapeutic Uses of the Acidum Phosphoricum Dilutum," by Judson B. Andrews, M.D., assistant physician in the New York State Lunatic Asylum, published in the *American Journal of Insanity*, for October, 1869).

In regard to the specific action of phosphorus upon the bones, Wegner says: "For the therapeutic application it is in general more advisable to make use of the phosphorus in substance than the phosphorous or phosphoric acids; if any considerable action is to be developed by the two latter preparations, they must be used in doses which, in animals at least, disturb the digestive apparatus to a high degree."

The officinal (U. S. P.) dilute phosphoric acid is very efficient in doses of 20 m. = 1·25 c.c. to 30 m. = 1·875 c.c., given three times a day. Such doses contain, the first about 0·65 gr. = 45 milligrams, the second about 0·98 gr. =

* Read before the American Pharmaceutical Association. From the 'Proceedings.'

68 milligrams, of phosphorus. The equivalent doses of uncombined or free phosphorus would be about $\frac{1}{60}$th to $\frac{1}{40}$th = 1 to $1\frac{1}{3}$ milligrams. Therefore the quantity of phosphorus given in the condition of phosphoric acid is nearly fifty times greater than when given as free phosphorus, to produce an equivalent therapeutic effect—provided the effect be the same—and not eight hundred to one thousand times greater, as in Wegner's experiments on the lower animals to obtain his effects upon the bony tissues. This part of the subject is much in need of closer investigation, and it is hoped that Dr. Andrews, or some other careful observer who may be equally familiar with the uses and effects of phosphoric acid, will compare it with free phosphorus, and give the results to the profession, when some means of accurate dosing of free phosphorus is afforded, as by the object of this note.

Referring, then, to the numerous authorities for what has been written on the subject of the effects and modes of administration of free phosphorus, it is here proposed to dismiss all the formulas for its administration, except that which up to this time may be conceded to be the best, namely, its solution in cod-liver oil, and to so formulate and elaborate this mode of administration that it may afford a safe and uniform practice as a basis for more accurate observation, and a more exact experience, and may enable the physician to prescribe, and pharmacist to dispense the substance accurately and conveniently in any dose, as with other articles of the materia medica, the object being to get the phosphorus into the stomach without oxidation, and yet in a condition to be all readily absorbed and active. A secondary object is to administer it in such a variety of forms as may adapt it to different conditions of stomach and palate, and render it as little disagreeable as may be consistent with the primary object of keeping it free from oxidation and active.

Solution of Phosphorus.

Take of Phosphorus, well dried	. . .	1 part.
Cod-liver Oil	. . . . . .	99 parts.

Put the cod-liver oil in a bottle which will be about three-fourths filled by it. Fit two corks to the bottle, set one aside and fit the other with two small glass tubes, one short and the other to reach to very near the surface of the oil when the cork is in the neck of the bottle. Then pass a current of dry carbonic acid (carbon dioxide) into the bottle, through the longer tube, for about fifteen minutes, or until the air is all driven out and replaced by the gas. Counterbalance a vessel of water on a good scale, and weigh into it the phosphorus, which has been cut into as large and as few pieces as possible, under water, in another shallow vessel, having one or two small pieces of phosphorus in excess of the exact weight required. Then put ice into the water with the weighed phosphorus, and set it aside for half an hour. Next, counterbalance a dry capsule, and add to the counterbalance the exact weight of phosphorus required. Chill the capsule well by immersion in ice-water, dry it, and replace it on the scale. Then take the pieces of chilled phosphorus from the ice-water, one at a time, dry them rapidly with a soft absorbent towel, or with good bibulous paper, and place them in the chilled capsule on the scale, until the exact weight of dry phosphorus is obtained. Then remove the perforated cork from the bottle, drop the pieces of dry phosphorus rapidly into the oil, and put in the unperforated cork which had been fitted and set aside. Set the bottle in tepid water, and warm the water until the phosphorus melts, and shake the mixture until the phosphorus is entirely dissolved, keeping it at about the same temperature till the solution is effected. Remove the longer tube from the perforated cork, and replace it with a siphon, the short leg of which shall reach to the bottom of the bottle, and then replace the cork in the bottle of solution. Connect the india-rubber tube of a self-regulating reservoir of carbon dioxide to the short tube of the cork, and put the pressure of the resovoir on to the bottle. Fit the end of the long leg of the siphon with a short piece of india-rubber tubing, and the other end of this tubing with a piece of small glass tubing about 2 inches (=5 centimetres) long, and put a pinch-cock upon the india-rubber tubing, the bottle being placed upon a stand some 6 inches (=15 centimetres) high. Then carefully open the pinch-cock and suck over the solution so as to fill the long leg of the siphon. Finally, by means of the siphon and pinch-cock, fill the solution into dry ground-stoppered bottles of not more than one fluid ounce (=30 cubic centimetres) capacity, allowing the carbon dioxide to fill the bottle from the drying apparatus of the reservoir as the solution is drawn out. In filling the bottles, the glass tube should pass to the bottom and the bottles be filled as full as is safe, leaving the least practicable room for air, and they should be at once tightly stoppered and be kept in a cool, dark place. The writer has found no way of avoiding oxidation and the formation of a pellicle, except by the use of carbon dioxide as above described, and no better way of accurately weighing and drying the phosphorus than that described. In all attempts to do without chilling, some fragment or the whole took fire before it could be properly dried and got into the oil.

This solution of phosphorus has the sensible properties of the cod-liver oil from which it is made, except that a slight odour of phosphorus is superadded, and the oil should be as limpid, as bland, and as free from odour and taste as possible, and must be entirely free from rancidity. When exposed to the air, it emits white vapour in small amount, and becomes covered with a dark-brown pellicle. This pellicle protects the oil below it from rapid change. In dispensing the solution from a one-ounce bottle, this pellicle forms after the first portion has been taken out, and increases in quantity to the last. It generally adheres to the sides of the vial, the oil from below breaking through it at each dispensing. No part of the pellicle should ever be dispensed. Nor should the last half drachm of the vial be used. The solution should be dispensed and the dose be calculated always by weight. It is one per cent. solution, and therefore each 100 grains contain 1 grain of free phosphorus.

Each minim weighs 0·88, or seven-eighths of a grain, and therefore represents 0·0088 grain of phosphorus.

This solution might perhaps be improved by previously decolorizing and deodorizing the cod-liver oil by filtration through carefully prepared animal charcoal; and also perhaps by adding to the oil say one-twenty-fifth of its weight of stronger ether, to give an atmosphere of ether vapour in the dispensing bottle for protection against air and oxidation. The writer has not had time to try these, but should they prove practically advantageous, he intends to adopt them in the preparation.

ADMINISTRATION OF THE SOLUTION.

Perhaps the best and most simple means of giving the solution is by a further definite dilution with cod-liver oil. If, as is not unfrequently the case, small doses of phosphorus are indicated in conditions which require cod-liver oil, or in cases primarily needing phosphorus wherein cod-liver oil would be a useful adjuvant, the following dilutions would be convenient:

Counterbalance a bottle containing a pint of cod-liver oil, and then pour into the oil 64 grains or 4 grams of the solution. This gives a dilution containing about $\frac{1}{50}$th of a grain or $1\frac{1}{3}$ milligrams of phosphorus in each half fluidounce or 15 c.c. of the mixture. A dose of two fluidrachms or $7\frac{1}{2}$ c.c. of this dilution, representing $\frac{1}{100}$th grain of phosphorus, given immediately after each meal, is very effective, and not very liable to interfere with digestion.

Four fluidounces of cod-liver oil weigh about 1700 grains or 110 grams. If to this be added 64 grains or 4 grams of the solution, each fluidrachm of the mixture represents $\frac{1}{50}$th grain or $1\frac{1}{3}$ milligrams of phosphorus. One, two, three, and four fluidrachms of this dilution severally represent the range of doses in which phosphorus is required, namely: $\frac{1}{50}$th, $\frac{1}{25}$th, $\frac{1}{16}$th, and $\frac{1}{12}$th grain, when active medication by phosphorus is indicated.

Mr. George C. Close, an able pharmacist of Brooklyn, makes an admirable emulsion of cod-liver oil, which is quite well adapted to either of these dilutions. The writer is indebted to Mr. Close for the following formulas and directions, which will be found very useful. The formula for an emulsion of cod-liver oil simply is as follows:

Take of—
Cod-liver Oil . 4f℥ = 1700 gr. = 120 c.c. = 110 grams.
Glyconin, . . 9ʒ = 540 gr. = 35 grams.
Arom. Sp. of Ammonia . . 1ʒ = 4 grams.
Sherry Wine . 20ʒ = 77·76 grams.
Tincture or Essence of Bitter Almonds.
(1 part Oil of Bitter Almonds to 64 parts Alcohol), 2ʒ = 7·78 grams.

Put the glyconin in a mortar and add the oil to it very slowly, triturating the mixture actively and constantly. The success of the emulsion depends upon the skill with which the first small portion of the oil is rubbed up with the glyconin, therefore the oil must be added in very small quantity and very slowly at first. After the oil is all in, add the other ingredients in the order in which they are named. In the large and successful use of this emulsion half an ounce of the sherry wine has often if not commonly been omitted, and the same quantity of diluted phosphoric acid substituted. The dose of this emulsion is from a dessertspoonful to a tablespoonful. Jamaica rum or brandy may be substituted for the sherry wine when preferred. Of all modes of giving cod-liver oil this is perhaps the least objectionable to most persons.

In using this formula as a vehicle for giving free phosphorus, the solution of phosphorus is made a part of the cod-liver oil. For example, take half the quantities of the formula, and for this four fluid ounce emulsion take 770 grains of cod-liver oil, and 80 grains of solution of phosphorus. Then a teaspoonful dose will represent $\frac{1}{40}$th grain of free phosphorus. Thompson says that oil of peppermint covers the taste of free phosphorus better than anything tried by him.

The glyconin which is so useful in emulsifying oils is made as follows:

Take of the yolks of eggs, carefully excluding the white, four parts; glycerin, concentrated and odourless, five parts. Beat or whip well the yolks of eggs in the usual manner, and pour the liquid into a bottle, add the glycerin and shake them well together. This glyconin keeps well for an indefinite length of time. It was introduced from French pharmacy many years ago, and as an emulsifying agent and preservative of emulsions, deserves to be better known. Emulsions made with it by ordinary skill and according to the above-given directions, never separate. If they separate it is for want of proper care in the commencement of introduction of the oil.

This solution of phosphorus may also be given in the form of a pill; and whether in pill, or the powder to be mentioned hereafter, it is always as a solution that it is given, since the solvent does not evaporate but remains to hold and protect the phosphorus. The formula for pills is as follows:

Take of the
Solution of Phosphorus, Magnesia, Powdered Soap, of each . . . 1 part.
Stronger Ether . . . . 2 parts.

Weigh the magnesia, powdered soap, and stronger ether in this order into a counterbalanced mortar. Stir the mixture until the powders are thoroughly wetted with the ether; make up the weight again by a little stronger ether to compensate the loss by stirring, and then weigh in the solution of phosphorus. Rub the whole together until the ether has all evaporated, and then divide the mass into pills, whose size shall be adapted to the dose of free phosphorus required. Dispense the pills in a vial into which a drop or two of ether has been dropped, to furnish an atmosphere of ether vapour for the better protection of the pills, and if any powder be used let it be magnesia. The pills should not be made in large quantity, nor be kept longer than a few weeks, as it is impossible to know how long the phosphorus will remain in a free state under the varying conditions to which such pills are subjected.

If the ingredients of the formula be taken so that each part represents 100 grains, that is, 100 grains each of the solution, magnesia, and powdered soap, and 200 grains of stronger ether, and if the mass be then divided into 100 pills, each pill will contain the $\frac{1}{100}$th of a grain of phosphorus, which would be the smallest usual dose. Such doses, taken three times a day, would require 33 days to use the 100 pills, and this is probably quite as long as they should be kept. The more common dose is $\frac{1}{50}$th of a grain, and then two pills would be taken at a dose, and the prescription would last seventeen days, and the pills would more surely remain in a proper condition.

Such pills, if it be desirable, may be dipped in a warm solution of 1 part gelatine in 16 parts water, and be dried in the usual way; and although this covers the odour of phosphorus, it is doubtful whether the coating is of much use as a protection against change.

The use of the ether in this formula is to drive out the air occluded in the powders, and supply its place with a substance which will not oxide the phosphorus; and if the formula be properly managed no white vapours are seen during the manipulation, nor in the vial in which the pills are kept, whether the pills be coated or not. As an experiment, a mass made as above directed was left exposed in the mortar for forty-eight hours without apparent change of colour, and without visible vapour, and the writer then took many doses of the pills made from it without eructations, or other digestive disturbance, the dose being $\frac{1}{33}$rd of a grain of phosphorus.

These pills are not luminous when broken open in the dark, because the oil protects the phosphorus from oxidation as well in the pill as in the bottle. The value of this common test for phosphorus pills is much overrated, since the shining in the dark shows oxidation of the phosphorus rather than protection, and a broken pill which does not shine in the dark may be either devoid of free phosphorus or may have it present in full proportion, but protected against oxidation. Again, the change which takes place in a broken pill may occur more slowly in an unbroken one.

This solution of phosphorus may also be given in capsules, and this method of giving it would be convenient and easy if it was practicable to get capsules, any large proportion of which were perfect enough to hold liquids. As a fact, however, they are so imperfectly made, as now sold, that but a very small proportion of them can be used for liquids, unless the plan of doubling the capsule be adopted by slipping one size moistened with water into the next larger size.

In dispensing this solution in capsules, the capsules can be conveniently and accurately filled by means of a 60 minim pipette, or by a cubic centimetre pipette. The pipette filled at the lower end by a piece of india-rubber tubing, and a piece of glass tubing drawn to a small orifice, with a pinch-cock upon the rubber portion. The upper end of the pipette is furnished with a piece of india-rubber tubing for suction. The whole being held upright in any convenient stand, the bottle is held so that the fine point dips into the solution. The pinch-cock being held open the solution is sucked into the pipette up to the top of the graduation, and the pinch-cock then closed. Then, by means of the pinch-cock, one or more minims may be rawn into each capsule. As each capsule is filled the dge of the cover is dipped into water before being put n. This seals the body and cover together, so that no akage ever occurs at that point.

Another way in which the solution is accurately, cononveniently, and easily dispensed, is in the form of a hoist powder.

If the solution be dropped upon any dry powder, and e rubbed up therewith, the air which the powder conains very rapidly oxidizes the phosphorus, as is shown y the copious white vapour given off, and by change in olour of the powder. But if the air be first driven out f the powder, the solution may be incorporated without ght or vapour or change of colour—the unmistakable igns of oxidation. This interstitial air is best driven out y ether. And the powders best adapted to the purpose re precipitated calcium carbonate, or precipitated calcium hosphate.

Counterbalance a one-ounce, wide-mouth bottle, fitted ith a good cork, and weigh into it 140 grains = 9·1 rams each of calcium carbonate and stronger ether. ork the bottle, shake it, and then add 5·3 grains = 3·24 rams of solution of phosphorus. Again cork the bottle, nd having shaken well, empty the contents into a ortar, and shake out all that can be shaken from the ottle into the mortar. Allow the bottle to stand unorked, that a portion of the ether may evaporate off. riturate the contents of the mortar until nearly all the ther has evaporated, and a damp powder remains. At he very first sign of white vapour, or before any vapour ccurs, transfer the damp powder by means of a spatula ack to the bottle, cork and shake it well, and then eigh it. The whole contents of the bottle should now eigh about 200 grains = 12·96 grams, that is, 140 parts alcium carbonate, 50 parts solution of phosphorus, and 0 parts ether, and this contains $\frac{1}{2}$ a part of phosphorus. f this powder 10 grains is equal to $\frac{1}{40}$th grain of phoshorus, 8 grains equal to $\frac{1}{50}$th, and so on. This powder ay be put into capsules, or better, into cachets or wafers, hus affording a good method of administration to those ho particularly dislike the odour and taste of cod-liver il. This powder appears to keep pretty well, that shown erewith having been made nearly a month. The porion made with calcium phosphate has, however, changed olour within the past few weeks. From being quite hite it now has a brownish tinge, a sure indication of hange. As the powders are not intended to be kept, ut must be made for each prescription, this is a matter f small importance. About twenty minutes of time is equired to make the powder properly, and the pharacist will not be likely to succeed well the first trial. ut when successfully done it will be found an excellent ethod of giving free phosphorus. Both powders, but pecially the calcium carbonate, have a tendency to comine with and neutralize any small proportions of the arious oxides of phosphorus that may form, and this is he reason for selecting these powders. Organic powders o not answer.

There are many patients whose stomachs will not olerate free phosphorus in any form, and a few that ccept it for a few days only; and much harm is often one by pushing it in such cases. If commenced in small oses, and never given on an empty stomach, but always fter a meal, it then disagrees, either by producing eructations to an injurious extent, or by interfering seriously with digestion, it should be abandoned, and be substituted y phosphoric acid; and this is no doubt the better agent or phosphorus medication in a large class of cases.

There are many patients, also, that cannot tolerate od-liver oil even in the smallest quantity. Such, too, had better be treated by phosphoric acid, for it has been pretty clearly shown that the solutions in vegetable oils, even when the oils are superheated beforehand, as well as the solutions in alcohol, ether, chloroform, carbon disulphide, etc., or in mixtures of these with or without glycerine, are liable to such changes as always to prevent accuracy in medication, and often to produce toxic effects. Even the solution in cod-liver oil has as yet not been tried long enough, nor with sufficient care and accuracy in its preparation or administration to justify the statements made in regard to it, and it is the object of this paper to place this solution under known conditions, favourable to accurate use and observation.

HYDROBROMIC ACID.

In answer to several inquiries to which the appearance of "hydrobromic acid" in prescriptions has given rise recently, we quote the following extract from an article by Dr. J. Milner Fothergill, which was published in the *British Medical Journal* for July 8 last:—

"The formula for the production of the acid in quantities of two quarts, is as follows. Dissolve ℥ x, ʒ vj., gr. xxviij. of bromide of potassium in four pints of water, then add ℥ xiij., ʒ j., gr. xxxvij. of tartaric acid. The bitartrate of potash is precipitated and the hydrobromic acid remains in a clear, bright, almost colourless fluid, possessing an acid taste and the ordinary acid properties as well as the peculiar properties of bromide of potassium, as compared with any other salt of potash.

"The accuracy of this last statement may be challenged by some readers; I will, therefore, briefly relate the conclusions arrived at after a twelve months' experience of the drug. It certainly does prevent the occurrence of headache, after each dose of quinine, in those who before had to desist from taking quinine for that reason. It is, perhaps, not invariably successful, but its power is very marked. It also prevents the fulness felt in the head by some persons, especially those labouring under cerebral anæmia, after doses of iron. It is also useful after nervous conditions, and, with quinine, is excellent in those cases when there is much nervous exhaustion from excessive indulgence in tea or in alcohol—this having been tried in a case of nervous excitability and sleeplessness where there had been much resort to chloral hydrate.

"In forms of excited action of the heart, connected with general nervous excitability or nervous exhaustion, hydrobromic acid is most useful; given with quinine (of which it is a capital solvent) and digitalis, it gives better results than bromide of potassium and digitalis" * *
"In all hysterical conditions connected with ovarian excitement, it seems to have all the properties of bromide of potassium. It is equally useful in the vomiting of pregnancy, and seems to exercise quite as powerful an influence over acts of reflex origin as does the bromide. It is especially adapted for the relief of menorrhagia associated with sexual excitement, and is even more effective here than the bromides themselves. It is also of use in whooping-cough, and combines conveniently with quinine, forming an effective measure in this troublesome affection; with spirit of chloroform and syrup of squill, it forms a most agreeable cough mixture of no mean potency. It is also of use in case of cough of reflex origin. When there is gastric irritability, it is the most useful of all acids, possessing the usual properties of acids generally and of the bromine as well.

"The dose of the acid, prepared as above, is one drachm as a full dose. Half a drachm is the dose I ordinarily employ. Hydrobromic acid has the further advantage of not producing the troublesome eruption so often the result of doses of the bromide of potassium, at least so far as my experience has yet extended. There are many qualities about this acid to render it a useful member in our therapeutical armamentarium. Dr. Wade* states that it is useful in the treatment of fever. It would seem the acid *par excellence* when there is much cerebral excitement in pyretic affections; but of this I have no personal experience."

THE CHINESE KNOWLEDGE OF COD-LIVER OIL AND IODINE.*

BY J. DUDGEON, M.D., ETC., PEKIN.

In the Chinese Materia Medica no fewer than thirty-one different kinds of fish with scales, and thirty-seven without scales, are mentioned. Among so many, it would be strange if certain therapeutic virtues belonging to some had not been discovered. The cod is not known in Chinese waters, so far as I am aware, and no oil is extracted from the livers of fishes. The Chinese, however, have found out that the use of fish and fish oil—particularly shad—is of service, and especially in consumptive cases. Phthisis is believed to be infectious. They account for it on the hypothesis that at the moment of death a worm is expelled, which enters the bodies of those in attendance, through the breath. To stamp it out, therefore, the patient, while yet alive, is sometimes put into a coffin, and buried or thrown into a river. This notion among the people is another way, most probably, of asserting the hereditary nature of any malady. The distinguished author (Lishechen) of the Puntsao or Chinese Herbal, who wrote over two centuries ago, mentions a case of this sort, as reported in another work, where several persons were so affected. The young lady in this instance was found floating in her coffin, in one of the great rivers, by a fisherman, and being taken on board and fed on shad, she recovered, and afterwards became his wife. Here we have the germ of our present cod-liver oil treatment. This fish is said to possess insecticidal and anthelmintic properties, and this is the Chinese *rationale* of its use in phthisis. For a similar reason it is also prescribed in fistula in ano, hæmorrhoids, etc. Oil of this fish if said to be a most certain cure in pityriasis versicolor, the cure being effected instantaneously with one application.

This same Herbal mentions various species of seaweed as possessing strong and well-known therapeutic properties, and of special value in the dispersion of hard tumours—goitre, for example. They have long been acquainted with the general virtues of the various species of *Laminaria*, and these varieties are mentioned as occurring along the coast of the Eastern Sea, the coast of Corea, and the Malayan Archipelago. The great Herbal speaks of seven chief species. The people in the maritime provinces of China eat seaweed plentifully, both medicinally and as a vegetable food, besides using it as a manure; in this custom resembling the inhabitants of our own Hebrides. It is prescribed alone, chiefly in the form of tincture, its saltish taste having been first washed away, or it is mixed up with other medicines in various prescriptions. Chinese books speak in the most positive manner of the discutient properties of seaweed. Of one sort, it is said that tumours as hard as stones can be softened and removed by it. The uses to which the various kinds of seaweed are put correspond with our own uses before the discovery of iodine. It is prescribed also as a diuretic, and its efficacy in demonology is highly extolled. (The Chinese in medicine, as in everything else, unite sober fact with childish fable, science with sorcery.) It is especially recommended in enlarged testicle and in all sorts of hard, cold, chronic tumours that never suppurate. It is said to cause penile erection. In glandular swellings it is ordered to be sucked or chewed. From the Chinese practice, the following questions suggest themselves:—Considering the high price of iodine and its preparations, and the disagreeableness and occasional indigestibility of cod-liver oil, which has been supposed to owe a part, at least, of its virtue to the presence of preparations of iodine and cognate principles, would it be advisable and advantageous to introduce a tincture and a powder of laminaria into our public dispensaries, poor houses, etc.? Is the Chinese contra-indication of fatty things well founded? After a course of iodine or its preparations are other diseases more easily induced?

* From the *Medical Times and Gazette*, February 17, 1877.

ASPARAGIN IN SWEET ALMONDS.*

M. L. Portes, in a paper published in the *Répertoire de Pharmacie* (1876, p. 641), announces the discovery of asparagin in sweet almonds. He noticed a peculiar crystalline crust to form on the outside of peeled almonds placed in absolute alcohol, and made a systematic series of experiments to ascertain the nature of the substance, as follows: 11,380 grammes of sweet almonds were divided into four portions, three of which were blanched, while one was left unblanched. They were then treated in the following manner: 500 grammes were placed in absolute alcohol, another 500 gm. in alcohol of 90 per cent., 250 gm. were placed in ether, and 8,000 gm. (unblanched) were put in alcohol of 90 per cent. At the same time 100 gm. of the skins, or testæ, were macerated in a fifth flask of absolute alcohol.

On the first day nothing particular was noticed in the first flask, but on the second day some crystalline grains, resembling sand, were observed to form on the kernels and walls of the vessel; two days afterwards these crystals became more numerous and settled to the bottom, while nothing similar was observed in the other vessels until the fifth day, when the same substance began to make its appearance in the second flask, increasing gradually in quantity as in the first. At the end of a week the contents of the fourth flask exhibited the same phenomena, but the crystals were much larger and less numerous. In the third and fifth flask, however, no change was observed, even after the lapse of a month.

It would therefore appear that strong alcohol, on penetrating through fresh, sweet almonds, eliminates from them a crystalline substance, which seems to reside almost exclusively in the cotyledons. It was further ascertained that dilution of the alcohol retards the appearance of the crystals, and that when alcohol of 60 per cent. is employed their formation is entirely prevented. Now, as subsequent examination proved these crystals to be insoluble in strong alcohol, the question arose, how alcohol could extract the substance from the kernels. The author's explanation appears to be the most plausible and rational one. He assumes that as the alcohol gradually makes its way into the interior it encounters and becomes mixed with the natural liquids of the kernel, and by displacing them causes them to pass outwards. This cellular sap, then, encountering a great mass of alcohol as yet unaltered and absolute, becomes mixed therewith, and as the crystallizable matter which the sap contains is insoluble in the menstruum, it becomes slowly deposited in a crystalline form upon the exterior of the kernels and upon the walls and bottom of the vessel.

After the formation of the crystals appears to be completed, if the whole be thrown on a strainer, and the crystalline substance be dissolved out by boiling water, a magnificent crop of crystals, resembling candied sugar, will be obtained on cooling or slightly concentrating the solution.

This substance was found to be but little soluble in cold water; easily soluble in hot water, hot dilute alcohol, ammonia, acids and acid solutions; insoluble in strong alcohol, ether, and fixed oils. These properties, together with its elementary constitution ($C_4H_8N_2O_3$, H_2O), and its crystallographic character, prove the substance to be asparagin.

IODIDE OF STARCH AS AN ANTIDOTE.*

Dr. Bellini, Professor of Toxicology at the Royal Institute at Florence, recommends iodide of starch as a valuable antidote in poisoning by alkaline and earthy sulphides, caustic alkalies and ammonia, and the vegetable alkalies. In poisoning by alkaline or earthy sulphides, he thinks it preferable to all other antidotes; in poisoning by caustic alkalies, it is applicable when acid drinks are not at hand.

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE INLAND REVENUE COMMISSIONERS' REPORT.

THE Nineteenth Report of the Commissioners of Inland Revenue, for the year ended March 31st, 1876, has recently been presented to Parliament, and as usual with such documents it contains many interesting items. From it we learn that the quantity of spirit charged with duty during that year amounted to 31,219,042 gallons, or upwards of 500,000 gallons in excess of the previous year. The returns of the quantities of home-made spirit retained for consumption as beverage in the United Kingdom shows an increase of 1·61 per cent. This increase appeared in the returns to be confined to England and Ireland, and by far the larger portion to be due to the latter country, the excess in consumption in Ireland beyond that of the preceding year being upwards of 400,000 gallons, or nearly 10 per cent. As regarded Scotland the returns showed an apparent falling off in the consumption of nearly 2 per cent., or 133,636 gallons. This was startling, and led to inquiries which showed that in Scotland a very large quantity of the spirit methylated was foreign spirit which had been charged with and paid duty to the customs, and which formed no part of the spirit charged by the Inland Revenue, although the whole quantity methylated is deducted from the spirit thus charged. So that on the whole it may be concluded that there was no real decrease in consumption of home-made spirit in Scotland. There has, however, been a continuous though slight falling off in the consumption of British spirit within the current financial year, 1876-7.

In the estimated consumption per head of all kinds of spirit in the United Kingdom England stands the lowest, the proportions being, England 1·114 gallons, Ireland 1·384 gallons, and Scotland 2·346 gallons. On the other hand the beer drinking capabilities of Englishmen are shown by an average consumption of 43 gallons of malt liquor per head, against 12 gallons per head drunk by Irishmen, and 14 gallons per head by Scotchmen.

During the currency of the licences for the year 1875, the latest included in this report, 152 distilleries in the United Kingdom used 882,679 quarters of malt, 112,808 quarters of unmalted grain, 3829 cwts. of sugar, and 120,799 cwts. of molasses in the production of 36,897,936 gallons of spirit. The quantity of plain foreign spirit entered for home consumption was greatly in excess of the preceding year, and came almost exclusively from Germany, from whence it has recently been imported at such low prices and of such good quality as to alarm the British distillers. On the other hand the quantity of British spirit exported shows little fluctuation, the average during tha past ten years being only 1,440,165 gallons. One beet-root distillery which had ceased working was in operation last year. The whole of the roots used were grown by the proprietor of the distillery, and the yield per ton was about the average.

Five cases of illicit distillation of cider dregs in the West of England were reported; this practice is said to prevail there when cider is plentiful, but there is no reason to think that it is on the increase.

As an instance of the close supervision that is necessary to prevent the Revenue from being defrauded it is stated that in certain warehouses a practice had become largely developed of racking spirits from one set of casks to another, and removing the emptied casks to other premises, where by the introduction of water the spirit absorbed by the wood was extracted and sent into consumption. This spirit, therefore, escaped payment of duty, and, although it might be supposed by those unacqainted with the scale on which bonding is carried on that this was a trifling matter, it was so far from being the case that in one warehouse alone it was estimated that the duty thus lost to the Revenue amounted to not less than £13,000 per annum; and in addition to this there was the further charge upon the Revenue of the salaries of officers employed in the superintendence of such extensive racking operations. In fact the extracting of spirit retained in the wood of casks is reported to be rapidly becoming a branch of trade, and stills are being erected for the purpose of recovering the spirit from the "grog" thus obtained.

The quantity of spirit methylated during the year ended March 31st, 1876, was 82,679 gallons. Nearly two thousand gallons of wood naphtha, intended for this purpose, were condemned by the Chemical Department as unfit for use. Some of it had been so highly purified and altered by chemical treatment that it was no longer capable of rendering spirit of wine sufficiently nauseous to prevent its improper use. A smaller quantity was found to contain 30 per cent. of ethylic alcohol, and turned out to be methylated spirit that had been distilled off from "finish." The quantity of purified naphtha imported from the continent has largely increased during the last few years, it being now largely used as a solvent in the place of methylated spirit. The imports amount to about 4,000,000 gallons per annum, of which only about 100,000 gallons are used for methylating spirit.

Numerous prosecutions are also reported to have been instituted for the sale as "finish" of methylated spirit which contained either no gum resin at all or a quantity far below the required amount of three ounces per gallon. The comment of the Principal of the Laboratory upon these cases is confirmatory of what has already been pointed out in this Journal. He says that the evidence revealed the fact that many makers of "finish" only add to the methylated spirit the exact quantity of gum resin required to be in solution, without taking any special trouble to get it dissolved. As commercial gum resins are not completely soluble in spirit, it is evident this quantity would not be sufficient, even if such care were exercised; but, in fact the spirit not being stirred or agitated to promote the solution of the gum, the greater part of it remains undissolved at the bottom of the vat. The number of licences issued to retailers of methylated spirit was 3552.

The licences to vend patent medicines issued numbered 15,022,—13,957 in England and 1065 in Scotland—and produced a revenue of £3798. The value of the stamps for patent medicines issued reached £117,649, being an increase of £8412 on this branch of revenue in the preceding year.

One curious point in connection with patent medicines had to be decided. In certain localities taraxacum root is sold mixed with coffee, and the mixture is recommended as yielding a beverage possessing medicinal as well as nutritive properties. Under the Chicory Duty Act this might have been allowed, subject to the same regulations as to payment of duty as are applicable to chicory. No duty, however, is paid upon this taraxacum, and the Commissioners felt it would be difficult to bring so common a weed under excise regulations. They therefore had to determine whether or not to treat taraxacum as an adulterant when found with coffee. It was eventually decided not to interfere with the sale of mixtures of coffee, chicory, and taraxacum, "if manifestly intended for a medicine, and properly labelled as such, by having a patent medicine stamp on each package, whether recommended for the cure of disease or not." But the substitution of roasted acorns for coffee, under the name of "pelotas" or surrogate coffee, not, we presume, exciting any therapeutic faith, was promptly stopped, and the manufacture has been transferred to Antwerp.

Another body used as an admixture with coffee that has been under the consideration of the Commissioners, is sugar, it having been represented that its presence during the operation of roasting preserved the aroma, and ultimately produced a more agreeable infusion. Having ascertained that not more than 3 per cent. of sugar would be requisite, the Commissioners decided not to interfere with this practice by the coffee roasters. A sample of "essence of coffee" examined in the Laboratory, proved to consist entirely of burnt sugar and roasted rye.

During the year five cases of disputed analysis were referred to the Chemical Department for fresh analysis, under the provisions of the Sale of Food and Drug Act. In two of these cases, one of whiskey said to be adulterated with wood naphtha and one of butter said to contain foreign fats, the conclusions of the Department differed from those of the local analysts, but in both cases the magistrates adopted them as conclusive.

In concluding our notice of this report we would remark that a false economy appears occasionally to lead to the rejection of lime and lemon juice. In some of the strongest samples, in respect to citric acid, hydrochloric acid is met with, and this is attributed to the use of casks which have previously contained salt provisions and have not been sufficiently purified. It was held that the juice being intended for use as an antiscorbutic, the presence of salt in it, even in very small quantity, is objectionable and sufficient to condemn the juice.

FORMATION OF A LOCAL ASSOCIATION AT CREWE.

A MEETING at which the whole of the chemists and druggists of the town were present, was held at the Castle Hotel, Crewe, on Thursday, the 22nd of February. It was convened for the purpose of giving the chemists and druggists of the locality an opportunity of coming to an arrangement to close their establishments at an earlier and more uniform hour than has hitherto been the practice. Mr. BAYLEY was voted to the chair, and a resolution was agreed to to the effect that half-past eight should be the closing hour, commencing on Monday, March 12th. After a little discussion a motion was submitted and passed that a Society, to be called the Crewe Chemists and Druggists' Trade Society, should be formed, of which Mr. McNEIL was elected Secretary and Mr. BAYLEY Chairman. It was also decided to adopt a price list and to use the recognized trade mark, viz. Mel Boracis. May we hope that this is only the thin end of the wedge and that the new Society will be able, after a time, to secure a still further reduction in the hours of labour?

THE EVENING MEETING.

THE next Evening Meeting of the Pharmaceutical Society, will be held on Wednesday, the 7th inst. A paper on a "New Source of Borax" will be read by Dr. PAUL, and one on the "Action of Chlorine upon a Beam of Light, and on the Preparation of Liquid Chlorine," will be read by Dr. A. SENIER. The chair will be taken at half-past eight o'clock.

FROM a telegram which appeared subsequently to the time of the last number of this Journal being sent to press, we learn that Messrs. FINZEL's Sugar Refinery at Bristol is closed for a few weeks only, as usual at this time of the year, for repairs.

IN the paragraph relating to the poisoning of pheasants by yew leaves, on p. 697, the last sentence but one should read, "Unfortunately for this theory, Professor TUSON is able to say that the yew leaves found in the birds examined by him were *not* those of the Irish variety."

Transactions of the Pharmaceutical Society.

EXAMINATIONS IN LONDON.

February 21st, 1877.

Present—Mr. Williams, President; Messrs. Allchin, Benger, Carteighe, Corder, Gale, Hanbury, Haselden, Linford, Martindale, Moss, Southall, Taylor and Umney.

Dr. Greenhow was present on behalf of the Privy Council.

MAJOR EXAMINATION.

Six Candidates were examined. *Four* failed. The following *two* passed, and were declared qualified to be registered as Pharmaceutical Chemists:—

Jones, George Marsh ....Sheffield.
Littlewood, John Oscroft ......Sutton-in-Ashfield.

MINOR EXAMINATION.

Fourteen Candidates were examined. *Seven* failed. The following *seven* passed, and were declared qualified to be registered as Chemists and Druggists:—

Ashburner, Isaac ....Broughton-in-Furness.
Avison, David ....Wakefield.
Bullen, George William ..... Newark.
Campbell, Charles ....Hull.
Gutheridge, George Frederick, Falmouth.
Hall, Edward ....Norwich.
Sykes, Henry ....Huddersfield.

February 22nd, 1877.

Present—Mr. Savage, Vice-President; Messrs. Allchin, Benger, Carteighe, Corder, Gale, Hanbury, Haselden, Linford, Martindale, Moss, Southall, Taylor and Umney.

Dr. Greenhow was present on behalf of the Privy Council.

MAJOR EXAMINATION.

Five Candidates were examined. *Two* failed. The following *three* passed, and were declared qualified to be registered as Pharmaceutical Chemists:—

Babb, James ... .Taunton.
Glover, William Kensit ....Aberdeen.
Peat, Joseph.......................Workington.

MINOR EXAMINATION.

Seventeen Candidates were examined. *Six* failed. The following *eleven* passed, and were declared qualified to be registered as Chemists and Druggists:—

Arblaster, Charles ....Birmingham.
Atwell, Benjamin Arthur ......Wincanton.
Batchelor, Alfred Ernest.........Fareham.
Cullingford, Louis James ......Bletchingley.
Francis, Rawson Parke ....Diss.
Hulland, Charles Richard ......Bath.
Mence, William Cookes ....Royston.
Peirson, Henry.....................Banbury.
Russon, Samuel Tonks ....Birmingham.
Shenstone, James Chapman ...Colchester.
Shilton, James ....Sutton Coldfield.

February 23rd, 1877.

Present—Mr. Williams, President; Messrs. Allchin, Benger, Carteighe, Corder, Gale, Hanbury, Haselden, Linford, Martindale, Moss, Southall, Taylor and Umney.

MINOR EXAMINATION.

Nineteen Candidates were examined. *Eight* failed. The following *eleven* passed, and were declared qualified to be registered as Chemists and Druggists:—

Allsworth, Norman ....Havant.
Dixon, Herbert.. ....Retford.
Edwards, Frederick William ...Bradford.
Fletcher, Redfern..................Newcastle-on-Tyne.
Gibbs, John ....Worcester.
Gregory, Frank....................Tunbridge.
Matthews, James Wavell ... ..London.
Rickarby, Arthur George ......Bromley.
Southee, William Jennings......London.*
Squire, Frederick John Cripps Plymouth.
Taylor, Charles Edward ....Lancaster.

MODIFIED EXAMINATION.

Two candidates were examined, *both* of whom passed, and were declared qualified to be registered as Chemists and Druggists:—

Oates, Edward Brooke...........Dewsbury.
Smithyman, Joseph ....Dudley.

PRELIMINARY EXAMINATION.

The undermentioned Certificates were received in lieu of the Society's examination:—

Certificate of the College of Preceptors.

Evans, Thomas Fryer ....Manchester.

Certificate of the Royal College of Surgeons of England.

Furmston, William Arthur......Wycombe.

Certificate of the University of Durham

Todd, Matthew James............Sunderland.

Certificates of the University of Oxford.

Crispe, James Herbert ....
Watts, Arthur Rugg ....Shaftesbury.
Wimpenny, John McMillan ...Waterloo.

EXAMINATIONS IN EDINBURGH.

February 22nd, 1877.

Present—Messrs. Ainslie, Borland, Gilmour, Kemp, Kinninmont, Stephenson and Young.

Professor Maclagan was present on behalf of the Privy Council.

MINOR EXAMINATION.

Eleven candidates were examined. *Three* failed. The following *eight* passed, and were declared qualified to be registered as Chemists and Druggists:—

Brown, Robert ....Leith.
Cassels, David Malloch ....Lanark.
Crook, Charles William Wallace Plymouth.
Dawson, Theo. Matthew Francis ...Hull.
Green, George ....Horncastle.
Keith, Alexander Reid ....Arbroath.
Mackenzie, George Grant ......Invergordon.
Stewart, Duncan ....Crieff.

MODIFIED EXAMINATION.

One candidate was examined, and failed.

Provincial Transactions.

LEEDS CHEMISTS' ASSOCIATION.

The fourth general meeting of this Association for the present session was held in the library on Tuesday evening, January 23rd, the chair being occupied by Mr. George Gell. After the minutes of the previous meeting had as usual been read and confirmed, Mr. Pick (of the firm of Smeeton and Pick) and Mr. Prust were duly elected members. A paper on "Volumetric Analysis in Pharmacy," of which the following is a *résumé* was then read by Mr. E. O. Brown.

In opening the subject a few general remarks were made in relation to chemical analysis, to the effect that it is divided into two main branches, viz., qualitative analysis which has to do with the finding out and recognizing elementary bodies, and with the methods of separating them from other substances with which they may be mixed or combined, and quantitative analysis which relates to the quantitative determination of a simple substance, or the relative proportions of simple or elementary substances, that may exist in a compound body. Two ways in which bodies may be quantitatively determined were then noticed, viz., gravimetrically *i.e.*, by weight, or volumetrically, *i.e.* by measure; the term by measure here implying that the weight of the substance is determined from the quantity by measure of the test solution used; or in other words the measure of the test solution required to convert a substance from a definite and known state to another equally definite state becomes a basis for calculating the amount of substance sought. Some of the conditions necessary for the successful application of volumetric analysis were then mentioned, such as the preparing of a test solution of known chemical power, and the using of accurately graduated vessels for measuring the test solutions. The completion of the reaction between the test solution and the substance sought must be apparent to the eye, or capable of being made so by the use of a suitable indicator. This may be by the ceasing to fall of a precipitate, as in the determination of bromide of potassium by nitrate of silver; or when chromate of potassium is used as an indicator, the appearance of the red chromate of silver marks the completion of the reaction, and the various ways in which the ending of reactions may be made perceptible were then noticed. The instruments and apparatus necessary for the conduction of volumetrical operations were next taken into consideration, also the relative utility of the metrical and British system of weights and measures. Volumetric analysis in its direct application to the testing of pharmaceutical preparations was next noticed, and also some of the preliminary operations necessary in preparing substances for the direct application of the test solutions. The estimation of some of the more important preparations of the Pharmacopœia was then practically demonstrated and the paper brought to a conclusion by a few remarks on the methods of calculating the percentage composition of the substances tested from the results so obtained.

The fifth general meeting was held in the library on Wednesday evening, February 14th, the President, Mr. Yewdall, occupying the chair. After the election of Mr. Harrison of Headingley as a member, Mr. Freshfield Reynolds occupied the evening with "Brief Notes on New Remedies." The subject was dealt with in a conversational manner and amongst the various drugs to which allusion was made, the following passed under review, and fine specimens were exhibited upon the table; viz., salicin and salicylic acid, boldo, jaborandi, rhamnus frangula, gelsemium sempervirens, eucalyptus globulus, guarana, coca leaves, ailanthus glandulosa, araroba or Goa powder, monobromated camphor, gurjun balsam, etc.

A cordial vote of thanks was passed to each author at the conclusion of the meetings.

MANCHESTER CHEMISTS AND DRUGGISTS' ASSOCIATION.

The second ordinary evening meeting of the session was held in the Memorial Hall, on Wednesday, February 21st, Mr. W. S. Brown, President, in the chair.

Messrs. Pontifex and Wood, of London, exhibited a set of pharmaceutical apparatus consisting of a copper boiler, tinned copper evaporating steam-pan and tin condensing worm; the working of the apparatus being explained by a gentleman who attended on behalf of the firm.

A paper was read by Mr. A. N. Palmer on—

Bisulphite of Lime and its Use in Brewing.

After some preliminary remarks the writer said that although the name Bisulphite of Lime was one that could by no means be brought into agreement with current chemical theory and nomenclature, it was, at the same time, a name that expressed well enough the fact that in the substance so called, lime was contained in presence of excess of free sulphurous acid. It was prepared on the large scale, by passing sulphurous acid gas into water having lime suspended in it until the lime was dissolved or the clear liquid had reached the required specific gravity. It was in fact a solution of sulphite of calcium in free dilute sulphurous acid. This was its composition when freshly prepared, but, no sooner was it made than it began to absorb oxygen from the air, so that it was impossible in practice to find a sample which did not contain sulphate of calcium as well as sulphite. Bisulphite of lime as met with in commerce varied, in respect of its important constituents, within not very wide limits. In the following table are given the percentages of the sulphurous acid gas (SO_2) and (in five of the cases) of the lime (CaO) that the writer had examined at various times. "A" was obtained from a wholesale druggist. B, C, D, and E were obtained from four different makers of bisulphite, and F, G, and H are distinct samples supplied by a fifth maker.

	Sp. gravity.	Lime.	Sulphurous Acid Gas.
A	1·056	—	4·45
B	1·070	2·38	5·38
C	1·060	1·96	4·73
D	—	2·241	5·779
E	1·070	2·39	5·82
F	1·060	1·78	4·76
G	1·048	—	3·90
H	—	—	5·46

Only of samples D and E were complete analyses made the results of which analyses were then given.

Bisulphite of Lime "D."

Sulphate of Calcium	·337 per cent.
Sulphite of Calcium*	4·508 „ „
Sulphurous Acid†	3·877 „ „
Water	91·278 „ „
	100·000

Bisulphite of Lime "E"

Sulphate of Calcium	·25 per cent.
Sulphite of Calcium‡	4·90 „ „
Sulphurous Acid§	4·11 „ „
Water	90·74 „ „
	100·00

Bisulphite of calcium was preferred by brewers to a solution of sulphurous acid capable of yielding an equal percentage of sulphurous acid gas, because in the first place the former was more stable than the latter, and because secondly its sulphurous odour was much less pronounced. The employment of sulphite of calcium rather than of sulphite of potassium or of sodium was due to its becoming transformed by oxidation in the beer to sulphate of calcium,—a substance whose presence in their brewing-water brewers always desired; while the use of bisulphite or of a solution of calcium sulphite in sulphurous acid was explained by the comparative insolubility of that sulphite in the brewer's worts.

The writer then described in some detail the uses to which among brewers bisulphite of lime is put, and the methods of its application. Beer, both in the process of its production and in the finished state, was liable to certain changes injurious to its character and quality, which, it was believed, could be absolutely prevented by the employment of bisulphite of lime. This was the case both

---

* Containing 2·774 per cent. SO_2
† „ 3·025 „ „ „
‡ „ 2·61 „ „ „
§ „ 3·21 „ „ „

when those changes were directly referable to the albuminoid substances of the beer, and when they were more properly expressed as the oxidation of the alcohol of the latter into acetic acid. The bisulphite of lime had of course an affinity for oxygen superior to that which alcohol or any other substance present in the beer had, so that whatever oxygen was absorbed went to that and not to these. By the use of bisulphite moreover, in his "working squares," the brewer could bring the fermentation process completely under his control. By the addition of this agent to a fermenting fluid, either the rate of fermentation could be diminished or the process stopped altogether.

It was also stated that when the primary fermentation with yeast was completed and the beer racked off into casks, many brewers were accustomed to add a further quantity of bisulphite of lime. The difference between beer which had been treated in this way and the same beer unbisulphited was said after a few days to be very apparent. When the former was sparkling, sweet and full-bodied, the latter might be quite flat, sour and thin. In beer in which the primary fermentation was completed, in fact, not all the substances in the original wort were fermented that were capable of fermentation. The beer contained these residual substances as well as a good many yeast cells. Fermentation thus went on more or less slowly in the casks, the beer diminishing in gravity and body, through the conversion of the extract-giving and toothsome sugar into thin and unsubstantial alcohol. Now the addition of bisulphite retarded this change and spread it over a longer time. Besides this, it prevented any such absorption of oxygen as would issue in the acetification of the alcohol of the beer. When properly applied and in due proportion, the sulphurous smell of the bisulphite was not perceived in the beer to which it was added. Indeed in the very act of working its effect it became transformed by absorption of oxygen into odourless products of change. These products—sulphate of calcium and free sulphuric acid—remained in the beer. As to the former of them, the formation of this substance in the wort during the process was positively advantageous if there were any grounds for the belief, widespread among brewers, that water containing a good deal of calcium sulphate was better for brewing than water similar in other respects, but lacking this ingredient. On the other hand, the fact, that, the use of bisulphite of lime, during and after the actual brewing-process, meant the presence in the finished product of about $1\frac{1}{4}$ grain of free sulphuric acid to the pint seemed generally ignored.

The writer in conclusion, referred to the use of bisulphite of lime for keeping such of the brewers' utensils as were not in constant use sweet and free from fustiness, as well as for recovering casks that had become partially "diseased."

After a short discussion, Mr. Payne proposed and Mr. Johnson seconded a vote of thanks to Mr. Palmer for his interesting paper. A cordial vote of thanks (moved by the chairman and seconded by Mr. Woolley) to Messrs. Pontifex and Wood for having gone to the trouble and expense of sending the apparatus for exhibition was also carried.

CHEMISTS AND DRUGGISTS' TRADE ASSOCIATION.

A meeting of the chemists and druggists of Newcastle-on-Tyne, Gateshead and district, was held on Thursday, February 16, 1877, at 7.30 p.m., in the long room, Neville Hotel, Newcastle-on-Tyne, in support of the Chemists and Druggists' Trade Association. Mr. Barnard S. Proctor presided, and there were upwards of forty persons present.

The Chairman, in the course of his remarks, said, fifty years ago there was no organization in the trade at all, but legislation of a troublesome character from time to time made its appearance, and the members of the trade were called together for self-protection and defence; meetings were held, but the temporary organization fell into decay again. This had been repeated more than once by the time the Pharmaceutical Society was formed. It originated out of troublesome legislation, but the wise men of that day saw that it was desirable to have a permanent organization of the trade, and they saw very wisely that the best foundation for a permanent organization was that they should work for the educational development and progress of the trade at large. They based their Society upon this point, because this was the object which would always be before them and which would invariably deserve their best efforts to promote. This was the reason the Pharmaceutical Society lived; it met a great want and a want that still continued to exist. After the Pharmaceutical Society was established, other organizations sprang up, and many died because they were based upon theoretical grounds, their want did not exist—in fact, they were born before their day. Besides local associations a united association came into existence; it sprang upon the theoretical ground that the Pharmaceutical Society was not doing what it ought to do; it sprang up in opposition to the Pharmaceutical Society, and it died because it had not a good work to do. He did not say it did no good; he believed it did a certain amount of good. Then the Co-operative Drug Society sprang up to give the trade the benefit of wholesale as well as retail profit without working for it. He did not say there was no profit in the wholesale trade, but he did not see any reason why the retail men should expect to get this profit without working for it, and it died because of its unreasonableness in this respect. Now they had a trade organization which afforded, among other objects, protection against co-operative traders selling and dispensing scheduled poisons; this was not a prominent object but it was one of the objects, which, together with others, their friends the deputation would explain to them, had brought this Association into existence, and if they felt satisfied with these reasons then it would be their duty to support this Association. He had alluded to a number of organizations which had failed, but besides those, he must allude to one which had succeeded, and succeeded immensely—he referred to the Pharmaceutical Conference, which originated some years ago. At the time there was a strong feeling that the Conference was got up in opposition to, and was destined to work not in harmony with the Pharmaceutical Society; this proved an entire mistake. It has been proved by experience that the Pharmaceutical Conference covered ground which the Pharmaceutical Society had not covered, and could not so well cover. It was still doing a good work and living, thriving, and prospering amazingly. The Pharmaceutical Society had also done much for the trade, but it had not done everything, and there was still much to be done. The most serious question arose as to whether the organization now proposed to be promoted could do, or would do, or would be more likely to do the work which the Pharmaceutical Society had failed to do. There most certainly was work to do. It remained for them to see whether the Pharmaceutical Society or the present organization would do the best or be most willing to do the work which yet remained to be done. He thought perhaps there was work for both to do. He would call upon the Secretary of the Association to state what he desired upon the point, and to give them more light in regard to this subject.

Mr. Haydon explained the history, aims, and objects of the Association.

Mr. Barclay then addressed the meeting on behalf of the Association, his arguments being substantially the same as have been reported on other occasions.

Mr. Councillor Owen considered the meeting was an indication that the chemists of the neighbourhood were really in earnest upon this matter. In recent days he had never seen such a large and capital meeting of the trade. Mr. Barclay had properly said that there must be united action between his Association and the Pharmaceutical Society, and unless they could see a fair chance of this union between the two societies he thought it was possible they might meet the same fate as some of the associations referred to by the chairman. He then moved a resolution approving of the formation of the Chemists and Druggists' Trade Association, and pledged the meeting to support the same.

Mr. Nicholson (Sunderland) seconded the motion, and said that they in Sunderland fully appreciated the advantages of the Association. He had no idea of the Association for one moment clashing with the Pharmaceutical Society, or he would never have joined it, because he belonged to the last-named Society, and he believed there was work for them both to do; and if properly conducted, they could both be worked together for the general advantage of the trade. The members of the Pharmaceutical Society could all become members of the Trade Association; they would then have the working of the Association in a great measure in their own hands. It would then rest with themselves whether or not the two societies should clash.

Mr. Mays (Shields) said he did not see why the societies should clash with each other, for like Mr. Nicholson, he was connected with both. He was sorry this milk of sulphur business had created so much stir, for he did not think it was worth it; he did not see why the public should not have the article they wanted.

Mr. Sharp (Sunderland) thought there was no fear of the two societies clashing. Their duties were essentially different, those of the Pharmaceutical Society being educational and those of the Trade Association being devoted to trade matters. In Sunderland they felt strongly upon trade matters, and they often held meetings on one point, that of juries. He thought they could fairly take credit that they were the first to agitate upon that matter as a public body. As a pharmaceutical chemist it did not affect him, but he sympathized with his brother chemists, numbers of whom he knew to be men who could ill afford to leave their business to attend juries.

Mr. Simpson said he had his own feelings in reference to this matter. His notion was, that after a little excitement and enthusiasm this Association would die out. There was not sufficient work in the trade for the continuance of a Trade Society. It was entirely different to the Pharmaceutical Society, which had a progressive work before it.

The Chairman said he would heartily rejoice when there was nothing left for the Association to do. He hoped they would hear something more of the opposition side.

Mr. Hall agreed with the Association in all its bearings. It was, in his opinion a most desirable institution to have. He urged the expediency of their banding themselves together.

Mr. Hogg (Shields) also spoke in support of the Association and urged that it was necessary to have protection. The Pharmaceutical Society did not serve all their purposes—it did not protect them in their trade, and he thought it quite time some society should be formed to look after these things He had great pleasure in supporting the resolution, and he hoped it would be unanimously accepted.

The Chairman then put the resolution to the meeting, and it was carried without a single dissentient.

After votes of thanks to the chairman and the deputation, the meeting terminated.

A general meeting of the chemists and druggists of Liverpool, Birkenhead and district, was held at the Royal Institution, Colquitt Street, Liverpool, on Friday the 23rd inst., at 3 p.m. About fifty persons were present.

Mr. John Abraham presided, and the President, Vice-President and Secretary of the Chemists and Druggists' Trade Association attended as a deputation from the Association.

The Chairman in opening the proceedings said he consented to take the chair, because he thought the members of the deputation were entitled to their best consideration, not only on account of the importance of the mission on which they came but also on account of their personal character. He asked for them the most favourable hearing, at any rate their most attentive hearing, and he hoped the meeting would carefully consider their propositions and debate them fully and freely. He must say he came to the meeting with somewhat mixed feelings. It had been supposed that the new Association which the deputation represented was somewhat antagonistic to some other societies previously existing. In the first place it had been supposed by some that it was antagonistic to the local society, that it was calculated to render the local society unnecessary, and that it would cease to exist. He must say he should very much regret that such should be the case. The local society was carried on at almost a nominal expense, it had done in the past, he thought, very material good, and if gentlemen were not pleased to come together and see what they could do for the common welfare a few times in the year he could only say they must be somewhat wanting in a sense of their own interests. The local Association had produced a very favourable influence upon the hours of business and he believed had greatly relieved some of the members and their families, and he quite expected that in the progress of the Society it would effect a further reformation in that direction, for he believed the long hours of business which prevailed in certain parts of the town were entirely unnecessary, and occasioned a great sacrifice of health and comfort on the part of the conductors of the business, and was of no advantage to the public or to the individuals. It had been supposed by some that the new Association would be antagonistic to the Pharmaceutical Society. He should very much regret if such was found to be the case, and he could not imagine that it would be so. The deputation would, no doubt, be able to satisfy the meeting upon this point. The Pharmaceutical Society was an organized body, with a Council elected in a manner in which every member had a voice, and it ought to be a true representation of the best interests of the chemists and druggists of the country. If it was not so it was the fault of those individuals who elected them. The Trade Association aimed at being a great body notwithstanding, but unless it was very extensively supported it could hardly be of the use which its promoters expected it to be. It must not only have a respectable income, but it must have very considerable influence, and he trusted that influence would be exerted in such a manner as to carry public feeling with it. Although it was a trade association he trusted it would not be found to be an association of trade interests against the public interests. He trusted it would be a protective association, and that it would be carried on with reference both to the most enlightened consideration in respect of economical and moral principles. The Association, he was sure, would not defend any man who wilfully and knowingly sold adulterated articles. He hoped it would claim to do nothing which interfered with that freedom of commerce which was one of the established principles of the age. He thought upon that point there was the most danger of disappointing many of its members. They had no right to expect any monopoly or any exclusive privileges, except such as were necessary for the public protection, and he was persuaded that if they sought such, they would be disappointed. The feeling of the age was altogether in a different direction. He trusted that the Association would be conducted in such a manner as to obtain the public confidence, as in the main the Pharmaceutical Society had done. He would now ask them to hear those gentlemen who had been deputed to attend the meeting.

Mr. S. U. Jones said the chairman in his opening remarks had clearly laid down, as nearly as possible, the views of the Committee of the Association, and what they really wished to do. They did not wish to create any monopoly serviceable to only one part of the community, they wanted to organize an extensive association to protect themselves when they were attacked from any quarter whatever. They had not the slightest idea of interfering with either the privileges or objects of the Pharmaceutical Society; he honoured that Society for what it had done, and for its Council he had the greatest possible respect. He should be sorry to say anything which would in any way annoy the members of the Pharmaceutical Council; when he appeared before that Council not long since he explained to them, and he thought to their satisfaction, that the Trade Association had no feelings whatever antagonistic to the Pharmaceutical Society, and he was treated with the greatest possible respect by the members of the Council then assembled. He thought, however, there were many things which the Trade Association could take up that could not be so properly or so easily dealt with by the Pharmaceutical Society. He might instance, in that respect, the prosecutions in the milk of sulphur cases under the Adulteration Act, and the prescribing cases at Nottingham; these were pure and simple cases of prescribing. They could, however, have no sympathy with men who wilfully broke the law, but men who endeavoured honestly and fairly to carry on their business should be protected by the Association. They had sent cautions to several persons on no account to prescribe out of their own shops, not to visit patients, or to take them into a back room which had the least resemblance to a surgery. They were prepared to take up simple cases of prescribing and have the matter settled in a proper and legal manner, and if the decision was adverse they should certainly appeal to a superior court. As to the local society nothing was farther from the mind of the Trade Association than to interfere with it in any way.

Mr. Haydon then explained the history, aims, and objects of the Association. In the course of his remarks he said that under the Adulteration Act when an official had made a purchase of a drug or preparation for analysis, he was bound to offer a third portion of the article purchased, duly sealed, to the vendor. He further impressed on the meeting the necessity of chemists invariably accepting this portion; it frequently happened they would refuse it, saying they had more in stock, but he wished to remind them that a sample not bearing the official seal of the inspector was of no value for an analysis to be submitted to a court of law. Three chemists were recently summoned before the Salford magistrates for selling balsam of copaiba said to be adulterated. Only one of these gentlemen accepted the sealed portion offered by the inspector; this on analysis was found to be pure, and the solicitor of the Association had been instructed to defend in this case.

Mr. Barclay next advocated the claims of the Association.

Mr. Turner moved a resolution approving of the formation of the Chemists and Druggists' Trade Association, and pledged the meeting to support the same by every means in its power.

Mr. Tanner seconded the resolution.

Mr. John Shaw said he had much pleasure in supporting the resolution. The formation of the Association commended itself to his views as being the best that could be done under existing circumstances. He hoped for the best results from the visit of the deputation to Liverpool. There had been several prosecutions in Liverpool under the Pharmacy Act, in some of which fines had been imposed and in others the business had been sold. He did not think the Pharmaceutical Society had neglected such cases on proper representations being made.

Mr. Mason said he had great pleasure in supporting the resolution; he had always strongly advocated the desirability of forming a trade association. With regard to the adulteration prosecutions at Salford he knew that the firm who sold the balsam of copaiba in one of these cases had had the article examined, and that it had been found to be pure.

The resolution was then put to the meeting and carried unanimously.

The proceedings concluded with a vote of thanks to the chairman.

THE REGISTERED CHEMISTS' ASSOCIATION OF LIVERPOOL.

The Annual Dinner of the above Association was held at the Adelphi Hotel on Friday, February 23, at 6.30 p.m., the chair being occupied by the President, Mr. John Abraham, and the vice-chair by Mr. Alfred Redford.

After the usual loyal toasts, the President proposed the toast of "The Registered Chemists' Association of Liverpool," coupling with it the name of the Hon. Secretary. This was followed by the toast of "The Chemists and Druggists' Trade Association," coupling with it the names of Messrs. S. U. Jones, Barclay, and Haydon. The Vice-President proposed the toast of "The Liverpool Chemists' Association," to which Messrs. A. H. Mason and Thomas Williams responded. Mr. J. A. Turner proposed "The Pharmaceutical Society," coupling with it the name of Mr. John Shaw. Mr. Hocken proposed "The Registered Chemists of Liverpool and Suburbs," to which Messrs. Fingland, Dickins, and Parkinson responded. The President next proposed "The Registered Chemists of Birkensend and District," to which Mr. A. Stewart responded. "The Wholesale Trade" was then proposed by Mr. Fingland, responded to by Mr. Barclay. Mr. S. U. Jones, of Leamington, proposed "The health of the President" which was warmly received. During the evening recitations were given by Mr. Alfred Tanner and Mr. Henry Jackson, and some good songs by Mr. A. H. Mason.

MEETING AT ABERDEEN.

On Tuesday night, February 20th, the chemists and druggists of Aberdeen held a conversazione in the Music Hall Buildings, the company, numbering between 200 and 300. Mr. James Paterson, wholesale druggist, occupied the chair.

The Chairman in opening the proceedings said: "Allow me to express the pleasure I feel in presiding on the present occasion, and at seeing such a large gathering. In these days, such meetings have come to assume the character of regular institutions among us, and, when well conducted, are calculated to be very beneficial. Our meeting to-night, if we manage to carry it out in the spirit in which it has been conceived, will, I trust, be both useful and instructive. I am glad that so many of the masters have taken an interest in the meeting, because the opportunities of social intercourse have a sweetening tendency. I have a kindly recollection of our society's annual dinner, and always regret that it was allowed to become defunct, believing that these meetings largely tended to harmony and good feeling. There will be the less to regret, however, if some such meeting as the present come in its place. A homely social meeting, such as this, must tend to bind master and assistant more closely together, and increase their mutual respect for each other in their different positions, and to foster and keep alive that kindly interest in each other, instead of the feeling which, in our day, is fast becoming traditional, that the relation of master and servant is on both sides merely a question of somehow doing so much work for so much pay." The chairman then expressed a hope that the meeting might result in some steps being taken for maturing a scheme for giving systematic instruction to the assistants with a view to enabling them to pass their examinations in pharmaceutical subjects at the end of their apprenticeship. After the passing of the Pharmacy Act the society did as far as in them lay to provide such a training; but somehow it was not taken advantage of. Wherein lay the cause of failure he knew not. This he could say, it was a fair and honest attempt on the part of the society to grapple with the subject. The feeling in the society now was, that it rested with the young men to take the initiative, and he was sure that, although a considerable amount was spent in that attempt in vain, they would be quite willing to lend a hand to any well-considered and feasible plan for carrying out this object. The necessity for some such scheme being carried was increasing daily. He was, therefore, the more anxious to take the opportunity of this gathering to impress upon them its importance with all earnestness. So far as his acquaintance among the young men went, they quite saw the necessity of studying, but yet he found a strong tendency to put the evil day as far off as possible, always postponing the time till they gathered a little more experience. The only remedy for this hesitancy was to institute a course of thorough and systematic training some time during the course of the apprenticeship, to enable them to obtain that mastery of the subject and confidence in themselves necessary for creditably meeting the examiner. "You will find," he said, "in after life, that the training thus given will be of immense advantage to you, not only as regards the technical knowledge acquired concerning your business, but in the mental training it gives, and will repay its acquisition at the cost of some present income. Now, while you are young, is the only time you can aquire such training successfully. If the opportunity is let slip, very probably it may never come to you again, and if it does, it will cost you the expenditure of far more time and labour than if acquired in youth. You know your own feelings in regard to these matters better than any members of the society can. You have the advantage of seeing wherein their scheme failed, and I sincerely hope that these few remarks may be the means of awakening a fresh interest in the matter, and that you will manage to bring it to a more successful termination than the last. The other point, on which I hope this meeting may ripen opinion upon, and which has a pretty close relation to the other subject spoken of, is the shortening of the hours of business. There can, I think, be no two opinions as to its desirability in the interest both of master and assistant. That an hour could be gained in the evening without either injury to business or inconvenience to the public, I have no manner of doubt. I have never heard any argument against it that has not been applied in almost every business into which early closing has been introduced, and yet the evil results somehow never follow. The gain to the masters would be greater than they think. In the conduct of a drug business there is, if not at any time a very strong, at least there is a constant and long-continued, although perhaps unconscious, mental strain, to which relief to the extent I have indicated would be felt, when fairly tried, to be a very great boon. Such has been my experience. When shorter hours were first introduced in the wholesale trade, I cannot say that I felt personally any necessity for relief; yet I am now sensible of the benefit it confers, and am satisfied that others feel the same. If our young men are to undergo the training necessary now for entering fully on the business, I think some shortening of the hours must be made, so that they may go to their studies with something of vigour and freshness left in them to digest and assimilate what they are being taught or are reading. It seems to me that this is a matter very much in your hands. Were a spirit of study and inclination to it shown, so that the master would feel with some degree of certainty that the time so gained would be well spent, this, I am sure, would go a long way to its being granted. You have every inducement to study. In subjects cognate to your daily business—such as chemistry, electricity, and others, in which much has been done—lie vast and unexplored fields, affording you ample scope both for instruction and amusement of a high and elevating character, and to the patient worker will one day open up secrets that will be for the benefit of mankind, and certainly not without considerable pecuniary advantage to the individual."

An excellent concert by amateur ladies and gentlemen was then given, and after the concert the company adjourned to the ball-room were supper was served, after which the circular room was thrown open for the inspection of a number of beautiful microscopic objects, which were laid out on tables, under the charge of Drs. Cameron and Simpson. The microscopes and the objects were kindly lent for the occasion by Professor Struthers, Mr. Clark, Old Aberdeen, and Mr. Lees, curator of the museum. Mr. George Miller, Sandilands, enhanced the exhibition by an appropriate display of interesting chemical products. After an hour's conversazione, the company repaired to the ball-room, where, to the music of an excellent band, the "dance gaed through the lichted ha'" very pleasantly for several hours.

Proceedings of Scientific Societies.

PHILADELPHIA COLLEGE OF PHARMACY.

A meeting of this College was held on the 16th of January, Mr. Dillwyn Parrish presiding. Mr. A. W. Miller read a paper on—

Adulterations.—The author stated that Oregon balsam of fir (so-called) appeared in the New York market several years ago. Professor Maisch then examined it, pronounced it to be of suspicious appearance, and raised the query: "Is such an article known on our Pacific coast, and if so, what is its source, and how is it obtained?" This inquiry can now be answered by stating that the article in question emanated from St. Louis, Mo., where it was manufactured by carefully melting two parts of the finest select white rosin with one part oil of turpentine. A small amount, generally about one ounce to five gallons, of oil of wormwood was subsequently added, this having been found to be most efficacious in completely disguising the ordinary terebinthinate odour. The "balsam" was then shipped to a prominent New York broker, who succeeded in selling considerable quantities of it, as the genuine article happened to be at that time unusually scarce and high-priced.

Sulphate of quinia, put up in the usual style of the American manufacturers, has heretofore been regarded as being above reproach. Even the lately much abused dealers in pure essential oils of New York contented themselves with operations in Pelletier's French quinia. The author's information is to the effect that a year or two ago in one of the Western cities the labels of American manufacturers were deliberately soaked off, after which an admixture of salicin was introduced. The label was then replaced and the article disposed of. Another somewhat more enterprising dealer in the same city had muriate of cinchonine manufactured on his own premises, and used this to adulterate sulphate of quinia to a large extent. In this case the preparation was put up in tin cans, without bearing the name of any manufacturer.

Italian essential oils, chiefly lemon and bergamot, were imported by a Western druggist to the extent of 100 cans in one lot. They were opened, sophisticated to an enormous extent, and again closed with false seals and brands.

While in the East, the adulteration of cream of tartar is almost entirely confined to grocers and spice mills, in the West the wholesale druggists also seem to indulge extensively in this fraud.

The labels and wrappers of English calomel have been successfully imitated in the West, and large amounts of this pseudo-imported chemical have been there disposed of.

Professor Maisch expressed satisfaction in having the source of Oregon balsam of fir cleared up. He stated that his previous experiments had convinced him that it was a fictitious combination of rosin and turpentine, but that he had not been able to recognize the flavouring ingredient. Professor Maisch remarked that years ago itinerant vendors had sold either pure salicin or mixture of salicin and quinia in proportions adjusted to the price realized, in various sections of the United States, under the garb of pure sulphate of quinia. He also spoke of the occasional adulteration of balsam of copaiba with castor oil, which is not very readily recognized, both being soluble in alcohol. Professor Wayne had suggested the use of petroleum benzin, as this dissolves copaiba quite readily, but castor oil very sparingly. This test is, however, fallacious, as mixtures of equal parts of castor oil and copaiba dissolve freely in benzin. A more reliable method is to distil off the essential oil, and then to examine the residue. Pure copaiba makes a transparent mixture with aqua ammoniæ, while castor oil will be indicated by a soapy appearance.

Professor Maisch read a lengthy paper on the use of the metrical system in prescriptions. He exhibited copies of the Greek and Mexican pharmacopœias; of the new appendix to the 'Swiss Pharmacopœia;' of 'Dorvault's l'Officine' and of the pharmaceutical journals 'Revista Pharmacia' and 'La Emulacion,' in all of which weights are employed, as indicated in the paper.

Mr. James T. Shinn desired to know what means were adopted in Europe in order to dispense with the use of graduated measures in prescriptions. Professor Maisch informed him that a special scale, one beam of which is often furnished with a rider, is usually reserved for this purpose. After the vial has been tared, the prescribed liquids are then weighed directly in it.

A communication from Mr. Hans M. Wilder was also read, advising a recalculation of the pharmacopœia quantities into parts by weight, and suggesting that it be left optional with physicians to prescribe either in grams alone or by grams and cubic centimeters, just so that they indicate it plain and legible. He called special attention to the necessity of great care in the marking of the decimal point, the position of which may often be a matter of life and death, as far as the patient is concerned. Professor Maisch stated that the same subject would claim the attention of the New York College of Pharmacy that week. Dr. Pile expressed a fear that it would prove difficult for physicians to adjust their doses by weight, on account of the differences in the specific gravity of liquids. Professor Maisch replied that practically only three classes of liquids deserved consideration in this connection, namely, water, syrups weighing one third heavier, and oils weighing one-tenth less than water; with most tinctures and fluid extracts, if prescribed as if they were of the same specific gravity as water, the difference would hardly be greater than the increase in bulk by dissolving solids, which physicians have very generally overlooked, but in those cases, where great exactness is desired and the precise size of the patient's teaspoon or tablespoon is known, the difficulty can be overcome by the addition of an adjuvant to make up a designated quantity. In answer to an inquiry, Professor Maisch stated that several American medical societies had recently advised their members to use the metric system in prescribing.

Mr. James T. Shinn thought that the looseness of physicians in the matter of doses justified the retention of the present system of measuring liquids as a matter of convenience. Professor Maisch regarded the appliances for weighing in pharmacies as productive of far more accurate results than the present means used by druggists for measuring. He considered the uniformity of the metric system all over the world as the most important argument for its introduction. Even in comparatively narrow glass tubes there is so much liability to error in reading off the space occupied by the liquid which is measured, that in analytical work a special indicator is made use of so as to reduce the apparent variation to its minimum. This error is enormously augmented in proportion as the diameter of the surface of the liquid increases. Mr. E. M. Boring alluded to another error due to capillary attraction in tubes of narrow diameter.

Mr. A. W. Miller suggested that physicians might write a formula for one single dose, leaving the adjustment of the diluent to the pharmacist, in order to make up the conventional teaspoon or tablespoonful dose. The physician could then readily prescribe any convenient number of doses by the usual subscription: *Misce tales doses no.——*. All the much dreaded labour of calculation and adjustment would thus be thrown on the druggist, who has certainly more leisure to do it carefully and accurately in the seclusion of his prescription department than the physician at the bedside of the patient.

Professor Remington referred to the action of the last committee on the revision of the Pharmacopœia, who had received positive instructions to abolish all measures of capacity, but on account of the obstinacy of some of their members, retained the majority of them. He saw no possible way of evading the issue, and therefore advocated taking the step at once, and doing it completely, without resorting to any half-way measures. He thought it wrong to wait for physicians to make a beginning. Professor Maisch enumerated the various nations who had adopted the metric system for use in medicine, showing that it was already in use on nearly the whole continent of Europe, in all of civilized America, excepting the United States and Canada, and in the empire of Japan. According to information obtained by him from the medical attachés of the Japanese Commission during the late Exposition, the entire system of medical and pharmaceutical instruction in Japan is modelled after the German method; they even use the same Latin terms, and pronounce them in accordance with the usage prevalent in Germany, and use the French weights exclusively.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A meeting of the above Association was held at 17, Bloomsbury Square, on Wednesday evening last, when a paper entitled "The Radiometer: What it is and a Few Facts connected with it," was read by Mr. C. J. Mead. The author, after a brief description of the radiometer as first constructed by Mr. Crookes, and some of its subsequent modifications, proceeded to recapitulate the theories that have been put forward in explanation of its movements, and the experiments by which they were supported. Mr. Crookes at first thought the motion of the arms was due to the direct influence of a property equally present in radiant heat and light, and which he termed radiation. Mr. Callado, however, noticed that the arms of a sensitive radiometer exposed to moonlight concentrated by means of lenses did not rotate. The light from phosphorescent powders was also found to be without effect. Neither was the movement caused by the blue flame of a Bunsen burner accelerated when the flame was rendered luminous. A radiometer subjected to the influence of an atmosphere, the temperature of which was higher than that within the bulb rotated until an equlibrium was established between the temperature inside the bulb and that immediately outside, and upon the source of heat being removed rotation took place in the reverse direction until the equilibrium was restored. In fact Mr. Crookes' later experiments have led him to the conclusion that the rotation is due to the internal movements of the molecules of unequally heated residual gas in the imperfectly exhausted bulb. The author concluded by pointing out the possible utilization of this instrument as a photometer and in other ways. The paper gave rise to considerable discussion at the close which a vote of thanks to the author for his interesting paper was unanimously passed.

Parliamentary and Law Proceedings.

The Charge of Personation at the Preliminary Examination.

At Bow Street, on Saturday, February 24, John Thomas Faulkner Colegrove was charged, on remand before Mr. Flowers, with procuring his registration under the Pharmacy Act by false representation; and Andrew Ritchie Hunter, formerly a clerk in the Savings Bank Department of the General Post Office, was charged as aiding and abetting, and the two defendants were for the first time also jointly charged with conspiracy. Mr. Douglas Straight, instructed by Messrs. Flux and Co., appeared for the Pharmaceutical Society. Mr. Straight commenced the proceedings by reading some letters and papers found in the possession of Hunter. Two were from a person (whose name was not mentioned) asking Hunter to pass the Preliminary examination for a friend, and saying that £10 would be given him, as that was his charge. A letter was also found on Hunter coming from and signed by Colegrove on the back of which were several signatures showing that some one had been practising an imitation of Colegrove's name.

Mr. Straight applied for an adjournment until Tuesday, in order that a warrant might issue for the arrest of the person who appeared in the correspondence read as introducing Colegrove to Hunter. The application was granted.

On Tuesday, the 27th, the prisoners were again brought up, and John Hinks was included in the charge. The letters previously referred to were read and evidence was given showing that Hinks had been in communication with Colegrove, and that he had that morning given himself up to the officer holding the warrant against him. The prisoners were then fully committed to take their trial at the Central Criminal Court. The defendants were admitted to bail.

Poisoning by Laudanum.

An inquest was held on Tuesday by Mr. H. S. Wasbrough, coroner for Bristol, on the body of Mr. John Cecil Wayet, aged 20, a medical student at the Bristol Royal Infirmary, who was found in a dying state in his room at that institution early on Monday morning. It was stated that the deceased suffered greatly from neuralgic pains, and that he must have taken an overdose of laudanum to obtain relief. Mr. Wayet was considered one of the most promising pupils in the infirmary. He was a son of the Rev. Field Wayet, rector of St. Stephen, Bristol.

The jury returned a verdict to the effect that the deceased came by his death through an incautious use of laudanum.

Review.

Handbook of Rural Sanitary Science, Illustrating the best Means of Securing Health, and of Preventing Disease. By C. F. Gardner; William Berry, L.R.C.P. Edin., M.R.C.S. Eng.; C. N. Cresswell, Barrister-at-Law; and Thomas Hennell, Assoc. Inst. C. E. Edited by Loby Marsh, M.D., M.R.C.P. London, M.R.C.S. England. Smith, Elder and Co. London: 1876.

The editor of this book offered, in 1875, a prize for the best essay on rural sanitary science, for which a number of gentlemen competed. The prize was secured by Mr. Gardner, and his essay is printed in full in the first five chapters of the work under review. The other essays were arranged for publication by the editor, and constitute the remaining three chapters, besides which the editor himself contributes some notes at the end of the book.

Notwithstanding the editor's attempt to prevent repetition of matter in the various essays as now published, there is a deal of it, and as the thesis by Mr. Gardner is undoubtedly the best we shall almost confine our attention to this part of the production.

After some introductory matter, the reader is led to look somewhat deeply into the sanitary aspects of rural districts, and a report by Bishop Frazer is quoted to show how necessary it is that we should not be deluded by the outside appearance of things. The cottages which, surrounded by pretty gardens and entwined by honeysuckles and roses, stand out like so many Elysian abodes, are generally ill constructed, and contain pregnant sources of disease. Thus it is related that in some, "one small chamber with the beds lying as thickly as they can be packed" serves as the sleeping apartment for "father, mother, young men, lads, grown, and growing-up girls." From such facts the author proceeds to show how utterly impossible it is that under such conditions people can live in a healthy and moral way. But, notwithstanding the truly repulsive facts which are given in this part of the work, we cannot by any means regard this state of things as universal, and indeed our experience would teach us that it is decidedly a state of exception, and we would go farther and submit that, as a rule, the English country folk are both clean and moral.

After enumerating the dangers to health of drinking impure water and breathing vitiated air, matters which are confirmed by various quotations from the reports of Mr. John Simon, it is laid down as a general rule that dryness and well-ventilated rooms are powerful means to prevent and retard such diseases as consumption. It is pointed out that the pecuniary loss to nations by reason of poverty and sickness is so great, that economists should be the most earnest sanitarians.

The second chapter is chiefly concerned with buildings, and the purity of air in or about them, and there is given valuable information regarding the best soils or foundations on which buildings should be erected. In connection with this subject it is pointed out that in damp districts it is a most useful measure to provide for a play or current of air beneath the ground floor of habitations.

Persons are warned against the use of arsenical wall papers; but in connection with this subject we are surprised to find no mention of the plan of varnishing wall papers, a plan which we think exceedingly good, and even economical in the long run. Varnishes are made with turpentine, and this substance here plays the same part as it does in wooden hospitals, and by its slow oxidation gives rise to influences which are most useful in preserving health. Not only so, but varnished walls or wall papers admit of ready and complete cleansing.

In treating of water-closets and so forth, the siphon trap is considered to be the safest and the best to employ, but as regards the dissemination of noxious gases into the atmosphere—anywhere out of the house—we do not quite agree with our author. From what is known of endemic disease, it is plausible that its communication takes place through the agency of actual matter, and from what we know it appears that this may take so finely divided a form as to float about in the atmosphere. When, therefore, we diffuse we by no means destroy, and in our opinion the only true safeguard consists in prevention by the judicial use of substances able to prevent the spread of disease. Cesspools are wisely condemned in this book, and earth-closets are recommended where water-closets are impracticable. Of the latter kind the tumbler closet, which is an automatic instrument, receives the greatest share of praise.

Mr. Gardner makes some useful observations on the subject of speculative building undertakings, and points out that while on such a wide scale the only object of the builder is to erect that which will sell, we cannot expect to get houses provided with the necessary accommodations for securing health, although a sham kind of comfort provision may prevail, and here it is that some kind of legislative interference is urgently required.

Where flowers are kept, either in houses or gardens, it is recommended that among them at least sweet smelling ones should be preferred. These sweet smelling ones are oil-secreting plants, and these oils generate peroxide of hydrogen (not ozone), which is a powerful disinfectant.

The third chapter is chiefly taken up with considerations on the disposal of sewage and the pollution of rivers.

It is asserted that the fertility of a farm depends in no mean measure upon the quantity of live stock kept upon it; but that while nearly one third of the live stock of this country is mankind, and while, therefore, we should anticipate on every ground a superiority in man as a manure-producing animal, it is not the case really. It is true that we do not make the most of ourselves, and further true that a certain branch of industry is therefore not carried to its possible extreme, but it is all the same in the end: we may not appreciate it sufficiently, although Liebig and others have so strongly dwelt upon the balance of things in nature. All animals consume oxygen and carbohydrates, and all excrete carbonic acid, water, and other products of life not so ultimate in their nature; time, however, is the factor which will bring about their decomposition into ultimate products, such as carbonic acid, etc., which serve for plant life in their turn, etc. It is possible for man to interfere, control, and quicken natural processes, but whether he does so or not, it is the same in the end. Do not let it be understood, however, that we shut our eyes to the necessity of a proper interference or a wise control; but what we do feel strongly is, that while it is attempted to realize large profits from such undertakings, so long will the attempts fail.

As regards the disposal of sewage, for country districts the plan of intermittent downward filtration is strongly recommended: the necessity for intermittent filtration being, that the whole process is essentially one of oxidation, and therefore the earth must be allowed from time to time to assimilate fresh oxygen; if not, the process becomes one of filtration only, and the object is not to be attained in this way.

The supply and storage of water constitutes the subject-matter of the fourth chapter, and the doctrine that water having been once in mixture with sewage is unsafe for human consumption, is laid down with emphasis. There are given some exceedingly useful observations on the utilization of water streams by means of reservoirs and a system of distribution; and after dilating on the use of the underground water bed, Mr. Gardner passes on to advocate a system of storage of rain water. It is proposed to effect this by constructing tanks on the roofs of houses, and when we consider that we have on an average an annual rain fall of thirty-two inches, we are struck with the fact that in this way a quantity of water of great use for cleansing and other purposes could be readily obtained. But we cannot go so far as the author does, in recommending the erection of such tanks on the tops of churches, etc.: "a thing of beauty is a joy for ever."

In the fifth chapter there are remarks on sanitary legislation and administration, in which the Public Health Acts of 1872 and 1875, and the Alkali Acts, occupy considerable attention.

As already pointed out, the remaining chapters are occupied with matters which have previously received attention, but we would remark that while in the essay by Dr. Berry (sixth chapter) it is strongly recommended that the Government should cause investigations into the nature of disease to be conducted, there is no mention of the researches which have been for a number of years conducted in various physiological and chemical departments under the medical officer of the Privy Council.

The notes furnished by the editor are thoughtful and suggestive, but do not call for special observation.

In conclusion, we take this opportunity as a seasonable one for offering an opinion on the kind of qualifications that officers of health should possess. Most of our medical officers are incompetent to properly discharge their duties as health officers, and this by reason of their education. It is, however, a chemical officer rather than a medical one who is required, for the knowledge that is mainly requisite is one of physiological and pathological chemistry in all its branches; and be it remarked that this is a science in regard to which most medical men are profoundly ignorant. Most of them know nothing about it, and but few know little, and we are convinced that so long as this branch of chemistry is suppressed in the hospitals and medical schools, so long will the present state of things continue. Whether officers of health should henceforth be chosen from the ranks of medical men is matter of opinion, but for our part we believe the duties could better be discharged by chemists. Yet it is not to be denied that chemists are as a body unacquainted with certain phases of knowledge which are equally valuable; in fact, the branch of physiological chemistry is greatly neglected even by them. What is wanted is a new class of men; the special faculties called into play by the duties of a health officer are ones which have not hitherto been associated, but which have been divided and kept distinct in the professions of chemistry and medicine.

Botanical Prize for 1878.

Sir,—As the season is close at hand when the Silver Council Medal is offered for the best Herbarium of British plants collected by students of pharmacy, I should like to make one or two suggestions concerning the regulations under which these herbaria are formed. I have before me a copy of the *Pharmaceutical Journal* for April 29th, 1876, page 875, where there is an article headed "Botanical Prize for 1877." I will treat each paragraph of this article in the order in which it stands.

On paragraph I., I have no suggestions to make.

Paragraph II. runs thus: "The collections to consist of British flowering plants and ferns, obtained in a wild state, and arranged according to the natural system; the collections to be accompanied by lists, arranged according to the same system, with the species numbered." In place of this I would suggest the following modification of it, viz., "The collections to consist of British flowering plants, ferns, lycopodiums, equisetums and charas, obtained in a wild state and arranged according to the natural system, following the nomenclature, sequence and numbering of the last (7th) edition of the "London Catalogue of British Plants" (published by Messrs. Hardwicke, 192 Piccadilly, price 6*d.*), the collections to be accompanied by copies of the catalogue with marks placed before the names of the plants contained in the herbaria, and the total number of species collected to be written at the end of the catalogue." My reason for adding the lycopodiums, etc., is that these plants are almost invariably treated of in books on flowering plants and are included in the London Catalogue. I think the advantage of using a standard list will be apparent to all. In the first place it will do away with all difficulty as to which plants are to be considered as species and which are to be treated as varieties, and will place each student on a similar footing; for under the present system the student who followed Bentham could only collect one Rubus and call it "Rubus fruticosus," where another who followed Hooker could collect some thirty or forty species which would all come under "Rubus fruticosus" in the former work; these remarks apply to numberless cases including the water buttercups, roses, willows, etc. In the second place for purposes of comparison, it will be a great advantage to have all the collections arranged by the same standard and in the same order. In the third place, the London Catalogue is a fair compromise between the views of different authors as to species and varieties and has been compiled with very great care and consideration, and by following such a list the student is not confined to any one work but in cases of difficulty can make use of the descriptions of various authors in determining his plants.

Paragraph III. runs thus: "The collector to follow some work on British Botany (such as that of Babington, Hooker, or Bentham), and to state the work which he adopts. The name of each plant, its *habitat*, and the date of collection to be stated on the paper on which it is preserved." In place of this I would suggest the following:—"The collector to consult such works as 'English Botany,' 'Babington's Manual,' 'Hooker's Student's Flora,' or 'Bentham's Handbook,' etc., and to state which works he has consulted. The name of each plant, its *habitat*, and the date of collection, and its number in the London Catalogue, to be stated on the paper on which it is preserved."

Paragraph IV. runs thus: "Each collection to be accompanied by a note containing a declaration signed by the collector, and certified by his employers, or a pharmaceutical chemist to whom the collector is known, to the following effect:—'The plants which accompany this note were collected by myself from wild plants, between the first day of May, 1876, and the first day of June, 1877, and were named and arranged without any assistance but that derived from books.'" Here I would make no alteration but would add at the end "and other herbaria." This I consider a most important addition, for it is practically impossible to determine many species from books only without the aid of authentically-named specimens for purposes of comparison, and if it be objected that this would give students living in large towns where there are good public herbaria, advantages which country students could not always obtain, I would reply that it is but a small set-off against the great advantages a country student has, who can run out whenever he has a spare half-hour and get a box full of plants, over one who lives in a large town and can only collect in his occasional half-holidays, or his summer vacation. The former can dry his plants at his ease and need not collect many at a time. The latter has to collect as many as he possibly can whenever he gets a chance, and often returns home with so many new specimens that he is quite bewildered as to how to dispose of them and get them named before they fade. When competing for this prize myself I often returned from a long day's walk thoroughly tired and had to sit up till one or two in the morning naming and drying my findings.

On paragraphs V. and VI., I have no remarks to make.

In paragraph VII. I certainly think the age ought not to be limited to twenty-one. What the limit of age should be is of course a matter of opinion. But as the Minor and Major examinations cannot be passed until that age is attained, I certainly think it a great pity to take from students the inducement to collect plants, and study botany in the most practical and thorough manner, whilst they are preparing for their examination. Collecting plants also takes them into the open air, and compels exercise, which is certainly a most important thing to those who are reading hard for an examination. If I may suggest what would appear to me to be a suitable limit as to age it would be twenty-four.

I must apologize for the great length of this communication but could not compress what I wanted to say into a much smaller compass.

FREDERICK J. HANBURY.

Plough Court, Lombard Street, E.C.,
February 27, 1877.

EDINBURGH CHEMISTS TRADE ASSOCIATION MEETING.

Sir,—The notice which appeared in the Journal last Saturday week, regarding a meeting held in Edinburgh under the auspices of the Chemists and Druggists' Trade Association, hardly gives a correct statement on a most important matter connected therewith. It is stated as one of the objects of the meeting that it was to consider whether a North British branch of the Association should be formed, etc.; such a proposal was neither intended nor considered, as this had been resolved a considerable time ago. It will be seen from the report, only one motion was submitted, which was simply expressive of hearty approval of the Association. Regarding the remarks "the proceedings which do not seem to have been very animated, were concluded within an hour." Truly a friend did not report it thus. Any one accustomed to ordinary meetings of chemists in Edinburgh would consider the attendance a fair average, while half of the animation exhibited that evening would materially improve them. The business of the meeting began shortly after half-past eight, and concluded a few minutes before ten, in order to allow the friends from the South to return by the 10.30 p.m. train.

JAMES MACKENZIE.

Feb. 22, 1877.

[*⁎* According to the circular of the Trade Association one of the objects of the Edinburgh meeting was to consider "whether an Association should be formed embracing" the counties of Edinburgh, Haddington and Linlithgow. In other respects also we believe our report was substantially correct.—ED. PHARM. JOURN.]

"*Gnol.*"—*Weissia controversa*; (3) *Tortula muralis*; (4) Probably *Bryum cernuum*; send some when the capsules are more mature; (5) *Ceratodon purpureus*.

"*Syrupus.*"—(1) *Hypnum confertum*; (2) *Tortula muralis*; (3) *Grimmia pulvinata*; (4) *Hypnum cupressiforme*; (6) *Bryum capillare*.

F. J. B.—(1) See Dragendorff on the rectification of essential oils, *Pharm. Journ.* [3], vol. vi., p. 649. (2) Cartier's hydrometer is constructed only for liquids lighter than water. In its scale 22° corresponds with 22° Baume, "but above and below this point the degrees of Baumé are diminished in the ratio of 16 to 15," (Watts).

"*Dispenser.*"—The Acid. Sulph. Dilut., B. P.

"*Chemist.*"—(1) Our reference was quite correct. (2) Browning for gun-barrels: blue vitriol, 4 ozs.; tinct. perchloride of iron, 2 oz.; water, 1 quart; dissolve, and add 1 oz. each of aquafortis and sweet spirit of nitre. The fluid to be rubbed on the barrel, previously well cleaned, and allowed to remain several hours.

G. W. G.—You will find the information asked for on p. 715.

C. G. B.—Bentley and Redwood's 'Elements of Materia' (Longman), Proctor's 'Practical Pharmacy' (Churchills), 12s.

"*Pharmaceutical Student.*"—See a note on "Pill Coating," in vol. iv., p. 953.

"*Chemicus.*"—Probably the solution of alkaline silicate commonly called "water glass."

"*Dispenser.*"—We do not know any solvent that would give a solution of neutral sulphate of quinine of the strength required. Perhaps a solution of the alkaloid in ether or alcohol might answer the purpose. Quinine dissolves in its own weight of ether and in less than ten times its weight of rectified spirit.

"*Circumambulans.*"—We do not think it is desirable to discuss the subject in these columns. Probably if you addressed your communication to the Secretary he would lay it before the Council.

M. H. Jones.—The suggestion has already appeared several times in this Journal.

A. E. Lomax.—You are recommended to address the questions to the editor of a medical journal.

R. Williams.—The proportion of one part of chloroform in nine of the solution is more than double the strength of the Pharmacopœia preparation, which will account for the separation on mixing with water.

ERRATA.—In the eighth line of the recipe for Tooth Stopping, No. 538, p. 706, *for* "pure gelatine," *read* "pure platinum." In the fifth line of the next recipe, for Essence of Musk, *for* "ad partes viginti quinque," *read* "āā partes viginti quinque."

COMMUNICATIONS, LETTERS, etc., have been received from Mr. Chipperfield, Dr. Mehu, Dr. Dymock, Dr. Hesse, Mr. Ashwell, Mr. Bailey, Mr. Stevens, Mr. Lomax, Mr. Atkins, T. H.

NOTES ON THE ACTION OF CHLORINE UPON A BEAM OF LIGHT AND ON THE PREPARATION OF LIQUID CHLORINE.*

BY DR. A. SENIER AND MR. A. J. G. LOWE.

Action of Chlorine upon Light.—The following experiments were made with the view of obtaining, if possible, from chlorine an absorption spectrum analogous to the spectra given by iodine and bromine.

Combustion tubing, to the ends of which plates of glass were fitted, was filled with chlorine gas. Through various lengths of such tubes—the longest being about nine feet—light was transmitted and examined by means of a two-prism spectroscope. No absorption occurred except what was due to the colour of the gas, that is to say, the spectrum was brightest in the green and yellow, the violet and indigo being more or less absent.

In the next place, chlorine gas under pressure was examined. The pressures varied, the greatest being about four atmospheres. The deepest stratum examined was two inches. As regards absorption, the results were again negative.

Finally we experimented upon liquid chlorine in strata varying in thickness from one eighth of an inch to one inch and a half. The only absorption observed was that due to the deep yellow colour of the liquid chlorine.

We have therefore failed to obtain an absorption spectrum from chlorine, and our experiments—which in part at least are new—go to confirm the results already obtained.†

The Preparation of Liquid Chlorine.—The preparation of this element in the liquid form from crystals of hydrous chlorine ($Cl5H_2O$) by the methods generally described is a somewhat tedious operation, but by the use of a cotton-wool strainer to remove the hydrous chlorine from its mother liquor we have been enabled to render the operation comparatively easy. We prepare liquid chlorine as follows:—A stream of chlorine gas is passed through a bottle, about two thirds full of water and surrounded by a freezing mixture of sulphate of sodium and hydrochloric acid. Care is taken to prevent the water from freezing, and frequent agitation accelerates the formation of the hydrous chlorine. When by the deposition of crystals the contents of the bottle are fairly thick, they are poured through a funnel into a piece of combustion tubing sealed at one end. A plug of cotton-wool, attached to the end of a piece of twine, is inserted into the combustion tube, and is slowly pressed downwards by means of a glass rod or piece of glass tubing. In this way, the crystals are separated from the chlorine water, and are compressed tightly in the bottom of the combustion tube, while the water fills the tube above the plug and is poured off. By means of the string the plug is withdrawn, when more wet crystals may be added and the process of straining repeated. The combustion tube should be placed in a freezing mixture from time to time. When sufficient hydrous chlorine has been collected, the tube containing it is surrounded by a freezing mixture, and carefully sealed within about two inches of the surface of the crystalline mass. When cool it is surrounded by wire gauze and heated in a water or air bath to from 100° to 150° Fahr. In the course of ten minutes the crystals will be completely decomposed, the liquid chlorine appearing below the chlorine water as a dense deep yellow oily looking liquid.

In conclusion we have to express our thanks to Professor Attfield for his kindness in allowing us to make the above experiments in the laboratories of the Pharmaceutical Society.

[*The discussion on this paper is printed at p.* 744].

* Read at an Evening Meeting of the Pharmaceutical Society, March 7, 1876.

† See, however, experiments of Gernez (*Comp. Rend.*, lxxiv., 660—662).

NOTES ON INDIAN DRUGS.

BY W. DYMOCK.

(*Continued from page* 550.)

PEDALIUM MUREX.—*Local Names,* KARONTA, *and* BURRA-GOKHROO.

A spreading low succulent plant, with oval-dentate obtusely pointed leaves; pedicels axillary, 1-flowered, shorter than the petiole; 1, 2, or more dark brown glandular bodies situated near the axils; flowers yellow; tube of corolla about one-inch long; fruit pendulous, about half an inch long, and quarter of an inch in diameter at the base, four-angled, with a straight spine at the base of each angular ridge, above the spines is a narrow portion which is inserted into the five-clawed calyx; when dry the fruit is corky, it is divided into two cells, the seeds are elongated, narrow, and four in number. The young branches, petioles, under surface of leaves, and immature capsules have a frosted appearance, which is due to the presence of numerous small, sessile, brilliant crystalline 4- to 5- partite glands. The substance of the fruit consists in great part of dense fibro-vascular tissue, forming a kind of four-winged nut; the corky part consists of delicate cellular tissue; when fresh it is green and succulent. The fresh plant has a peculiar disagreeable musky odour. Simple agitation of the young branches in water, without any crushing produces a viscid mucilage, like white of egg. I find from experiment, that the glandular crystalline bodies described above, are the source of the mucilage; if they are gently scraped from the under surface of the leaf and mixed with water the viscidity is at once produced. The mucilage has a faint peculiar taste, but is not disagreeable; its properties have been sufficiently noticed in the Pharmacopœia of India.

VITEX NEGUNDO.—*Local Name,* LINGOOR.

The habit of this shrub is variable; when growing near the sea it has almost always 3-foliolate leaves, the leaflets being attenuated into the petioles. Inland, the shrub has a more delicate appearance: the petioles of the leaves are much longer; the leaflets are lanceolate, from 3 to 5 in number and often serrated; the flowers do not vary. The serrated variety is preferred for medicinal purposes, and is called Kâtree. The leaves of both varieties appear to me to be equally aromatic; the odour reminds one of the English Bog Myrtle; the taste is bitter and nauseous. The fruit is like a peppercorn, and very feebly aromatic. The *V. negundo* and *V. trifolia* of the Pharmacopœia of India will, I expect, prove to be but varieties of the same shrub. In Anthony Colin's

French translation of Clusius, Lyons, 1602, there are figures of both plants, which though old and quaint, represent the general appearance very fairly.

SMILAX OVALIFOLIA.—*Local name*, GOOTEE.

This climbing shrub is very common in the Concans. The roots are very numerous, and have a general resemblance to sarsaparilla. A section shows a dry, tuberous, brown bark; secondly, one row of 5-sided yellow cells which are more or less wedge-shaped, their nuclei being situated towards the apices; thirdly, a range of numerous rows of ovoid cells, variable in size, with central nuclei; these extend as far as, and partially surround, the vascular zone, which consists of large vessels with generally two smaller ones in contact with them. Within the vascular zone the central portion of the root is made up of large thin-walled cells filled with starch or red colouring matter; the latter is most abundant in young roots. Gootee is not used in Bombay, but in Goa it is kept in all the shops, and is the sarsaparilla of the Portuguese.

JATROPHA CURCAS.—*Local name*, MOGHLI ERENDI.

The young roots of this tree are soft, fleshy and tapering, with a whity-brown scaly epidermis, and a few thin rootlets; bark yellowish white internally, with a peculiar perfume, like tuberose, when freshly removed; wood white and very soft. On section the bark is seen to contain oil globules, and very numerous conglomerate raphides; the vascular system appears to be full of a yellowish viscid secretion; the woody portion is loaded with starch. Jatropha root bark has an acrid taste, like fresh mezereon; it is applied externally in rheumatism. The milky juice of this tree is worthy of remark; it dries into a brilliant transparent varnish of the colour and consistence of shellac, and is used by the country people like collodion, to close cuts or wounds.

MESUA FERREA.—*Local name*, NAGCHUMPA.

This handsome tree, with its large cistus-like flowers, is found in the Southern Concan and Goa territory, but is much more abundant further south. The dry blossoms are known as Nagkesur in the bazaars. The bark contains much resinous juice, which exudes freely when it is wounded. The root bark has a reddish brown epidermis, consisting of ten or more rows of brick-shaped cells, full of condensed resin. Within the epidermis is a variable number of rows of cells of the same shape, yellow, refractive, and containing resinous juice. The medullary rays are also yellow and refractive. There are numerous large laticiferous vessels. This bark is mildly astringent and feebly aromatic; it is not bitter as stated in the Pharmacopœia of India.

CALYSACCION LONGIFOLIUM.—*Local name*, SURINGEE.

The dried buds of this tree are known in commerce as Tamra Nagkesur (red nagkesur).

MICRORHYNCHUS SARMENTOSUS.—*Local name*, ALMIRAO.

Stem filiform, procumbent, bearing roots and leaves here and there; leaves crowded, sinuate-pinnatifid, lobes obtuse or subacute; peduncles rather shorter than the leaf, having at the top scaly bracts which are scarious on the margin. ('Bombay Flora,' Page 132.)—This plant has fleshy roots about the size of a crowquill and 6-8 inches long; when fresh they are yellowish white. A section shows a yellow central fibro-vascular column, containing very large fenestrated vessels arranged in a radiating manner. Beyond the radii the parenchyma is loaded with large colourless bodies of irregular size and shape, which gradually diminish in number towards the cortex where the parenchyma is not occupied by them. The cellular structure is delicate and the cells large. These bodies appear to be cells distended by some solid, nearly transparent matter, as they always correspond in form and position with neighbouring empty cells. This plant is much used in Goa as a substitute for taraxacum.

HYDNOCARPUS INEBRIANS.—*Local name*, KOWTEE.

Abundant in the Concans some distance to the South of Bombay, also in Goa. The oil is extracted for burning, and is also in repute as a remedy for skin diseases. It is at present on trial here as a substitute for chaulmogra; if found to be efficient it can be delivered in Bombay for less than half the price of the latter oil. It appears that the greenish tinge which the oil sometimes has is caused by the adherence of some of the pulp of the fruit to the testa of the seed; the pure oil from decorticated seed is of a pale yellow. The external appearance of the fruit varies considerably; upon the same tree perfectly smooth and very rough fruit may be seen.

SIDA ACUTA.—*Local name*, TUKATI.

The root of this plant is in general use as a diuretic and demulcent; it can hardly be classed as a bitter. I found it in all the Goa shops. It appears to be more used there than in Bombay. The root is small, woody, and fibrous, the stock not more than ¼ of an inch in diameter. The bark is of a light yellowish brown colour. *Sida cordifolia* is sometimes used for the same purpose. The lower part of the stem with a few leaves attached may always be found in parcels of these drugs and enables them to be distinguished one from the other. *S. acuta* has smooth lanceolate and serrated leaves. *S. cordifolia* cordate and tomentose leaves.

ÆGLE MARMELOS.—*Local name*, BEL.

The liquid extract is best prepared from the rind of the fruit only; made in this way it keeps well and does not become too thick. The pulp is too gummy to make a nice preparation.

ZANTHOXYLON RHETSA.—*Local name*, CHIRPHUL.

The capsules are similar in appearance to those of *Z. triphyllum* but a little larger. They have the same properties. The root is used in Goa as a purgative. It is of a yellow colour, and has a yellowish brown corky bark.

ANACARDIUM OCCIDENTALE.—*Local name*, KAJOO.

The acrid oily principle cardol is prepared in large quantities in the Goa territory during the process of roasting the nuts, and is used for tarring boats. I purchased twelve gallons at a country fair for Rs. 3

The Portuguese consider the spirit obtained from the torus to be a valuable diuretic, and apply it externally in rheumatism.

ERRATA.

Vol. vii., page 3, line 5 from bottom, for "Gowik," read "Gorukh."

Vol. vii., page 110, line 11 from top, for "Cuscuta reflexa" read "Cassytha filiformis."

Vol. vii., page 309, line 7 from bottom, for "Lamtanee" read "Parwel."

Vol. vii., page 309, line 4 from bottom, for "Ailanthus excelsa" read "Cinnamomum Tamala."

Vol. vii., page 491, line 31 from bottom, for "Lumetorum" read "dumetorum."

Vol. vii., page 491, line 3 from bottom, for "Airwan, Mairwan," read "Airwan-mairwan.

Vol vii., page 492, line 8 from bottom, for "Triphulli" read "Chirphul."

(*To be continued.*)

NOTE ON A PIPER, CALLED JABORANDI, IN THE PROVINCE OF RIO JANEIRO.*

BY A. GUBLER.

Besides the jaborandi of Dr. Coutinho (*Pilocarpus pennatifolius*), the sialogogue and sudorific properties of which are so remarkable, there exists in Brazil, as is known, a large number of plants bearing the same popular name, which are used against the bites of serpents, etc. All the botanical species, however, are included in two families, Rutaceæ and Piperaceæ. Among the latter, *Piper citrifolium* and *P. reticulatum* have been mentioned as particularly efficacious. A jaborandi from the province of Rio Janeiro, which has been the subject of a note in the *Journal de Thérapeutique* for November 25, by Professor Gubler, appears to be referable to either of these species, which perhaps should be combined in one.

The plant is a shrub, usually attaining, but sometimes considerably exceeding, a metre in height. The stems are fasciculated at the base, simple, and denuded for half their length, cylindrical, very straight, and articulated like the bamboo; towards the top they bear dark green leaves that are alternate, shortly petiolate, oval-lanceolate or slightly obtuse. In the axils of these are sometimes found catkins of male flowers. The figure of the plant, which by the courtesy of the publishers of the *Journal de Thérapeutique* is reproduced on the next page, is from a sketch drawn by Dr. Jules Crevaux. A supply of the plant, collected by Dr. Da Veiga, of the Brazilian navy, accompanied the sketch, and has been investigated chemically, physiologically, and therapeutically.

According to Professor Gubler the entire plant exhales a slightly aromatic odour, which becomes more pronounced upon bruising the leaves between the fingers. When chewed the taste is at first slightly acid, then warm and aromatic, and finally very piquant, and comparable to that of pyrethrum root. This taste is met with in the stems, and especially in the roots, where it attains a high degree of intensity, chiefly in the moderately large portions, about the size of a crow quill, which are externally of a rather decided grey colour. The more slender and whitish portions are rather insipid, and the finest have hardly any taste at all. These differences are dependent upon the constitution and thickness of the cortical layer, which appears to be the seat of the active principle.

When a picked fragment of the root is chewed, at first no sensation is produced on the palate; the prickling is first manifested at a short interval after the vegetable tissue becomes impregnated with saliva. It would appear that the active principle of the drug does not exist ready formed in the plant, but is due to a special fermentation in the presence of water, similar to that which sets free oil of bitter almonds or oil of mustard. When once manifested, the piquancy rapidly acquires great energy, being accompanied by painful shootings and vibratory tremblings of the tongue and lips, as though these organs were traversed by an electric discharge. At the same time a very active secretion of all the buccal glands becomes developed and especially an extraordinarily abundant salivation. These phenomena persist for a few moments after the sapid pulp has been rejected, but then decrease and disappear, leaving a sensation of freshness and a certain degree of anæsthesia of the palate. After a few minutes, however, all the parts return to their normal state.

Upon swallowing the saliva charged with the active principle, an impression of heat is produced at the back of the throat, which extends to the œsophagus and stomach, where it gives rise to a sensation resembling hunger.

The chemical composition has been studied by M. Hardy, who in some preliminary experiments with infusions was able to demonstrate the presence of an alkaloid.

Some leaves and stalks were therefore powdered, and left to macerate for four days with three times their weight of 90° alcohol, acidulated with eight grams of hydrochloric acid per litre. The alcohol was then decanted and fresh alcohol added, and this was repeated three times. The alcoholic solutions were concentrated by distillation, and the aqueous solution evaporated and decomposed by ammonia in the presence of excess of chloroform. Upon evaporation of the chloroform the base was left free, but still impure. It was therefore treated with water acidulated with hydrochloric acid, which dissolved the major part of it; the solution was filtered, evaporated, and again decomposed by ammonia in the presence of excess of chloroform. Upon evaporation of the chloroform solution the base was deposited, having a crystalline appearance and slightly yellowish tint.

The base presents the characteristic reactions of alkaloids; its solution give a white precipitate with iodide of mercury and potassium, and with iodine in iodide of potassium. Another portion of the leaves was distilled with water to obtain the volatile oil, but only a small quantity was collected, insufficient for investigation.

The alkaloid dissolved easily in water slightly acidulated with hydrochloric acid, and such a solution was used by Dr. Bochefontaine to study its physiological action upon animals. He found that it did not act upon the heart, or influence the muscular contractility; it was not a convulsivant. It appeared to have the power to prevent the mechanical or electric excitations of the mixed nerves, such as the sciatic, from being transmitted to the muscles. It appeared even to possess the paralysing power at the

* *Journal de Pharmacie et de Chimie* [4], vol. xxv., p. 128.

outset, and this property would seem to distinguish it with curare. Indeed, the paralysing action of curare is usually preceded by some slight spasmodic movements, which have not been observed in frogs poisoned with the alkaloid of false jaborandi.

Professor Gubler remarks that the effects observed after the administration of the plant to the human subject, although in small doses, had not led him to expect so violent an action from the alkaloid of the Rio piper. The first experiment, in 1875, with the comparatively fresh plant, did not reveal any great activity compared with the excessive power of *Pilocarpus pennatifolius*. Besides the peppery sensation in the mouth and throat, and the heat in the stomach, doses of four to six grams of the leaves in infusion only caused slight salivation and diaphoresis. More recent experiments have been still less fruitful. In a case of acute albuminous nephritis its effects were absolutely *nil;* whilst in the same patient on the following day, an infusion of four grams of *Pilocarpus* jaborandi in 200 grams of water caused abundant salivation and sweating, and an increased excretion of urine.

From these negative facts Professor Gubler draws the following conclusions:—

(1) That there exists a striking difference between the mode of action of *Pilocarpus pennatifolius* and of *Piper reticulatum.* With an insignificant topical action the *Pilocarpus* manifests a diffused action of great energy; the second, though very aggressive to the organs at the entrance to the *primæ viæ*, appears to be nearly inert when it once enters the circulation.

(2) That this inertia of the *Piper* is more apparent than real, and due to the insufficiency of the doses employed. In future it will be desirable to administer larger doses of the leaves, or, better still, of the root, to obtain physiological effects.

But if the alkaloid discovered by M. Hardy is a certain test of the efficacy of the *Piper reticulatum* the experiments of M. Bochefontaine show that it will be advisable not to seek to obtain the first manifestations through the secretions, as the new agent is a poison of the motor system closely allied to curare.

PHARMACY IN SOUTH AMERICA.*

BY PROF. C. GILBERT WHEELER.

There is much similarity between the various republics of the southern hemisphere as regards pharmacy; Italian and French systems seeming to be the models, accepted at least in very many of their leading features. The republics where general culture and intellectual activity stand the highest, make also the best show regards the condition of pharmacy. Foremost should be placed the Argentine Republic and Chili; the first place being accorded to the former country. I shall therefore go into detail only with relation to the Argentine Republic.

PHARMACY IN THE ARGENTINE REPUBLIC.—The pharmacists of the Argentine Republic are chiefly foreigners, mainly Italians, although the proportion of natives is steadily increasing. In 1875 there were 224 persons who had a licence to carry on the business, and of these but 68 were natives. About 70 pharmacists are in Buenos Ayres. There are a good number of French and German druggists, also a few English ones in the larger cities.

The business is indirectly under government control and supervision. The awarding of licences to pharmacists is, after an examination, the business of the faculty of the government school of medicine. The annual examination of the drug stores is attended to by the board of health. Provision is made by the government for a

* Read before the American Pharmaceutical Association.

regular preliminary and also a professional course of training for pharmacists. Thus, unlike most countries of continental Europe, there is no limit set to the number of pharmacists who may establish themselves in a given town or city. Each pharmacy, however, must be represented by a pharmaceutical chemist, although it is not required that he give personally his attention to the business. As his licence does not contemplate any particular location, he is at liberty to open branch establishments wherever he may choose. This concession has led to an abuse, towards correcting which earnest efforts are now being put forth. This grew out of the circumstance that parties holding a licence to practise pharmacy would open branch establishments at various points and, giving no personal supervision themselves, would leave them in charge of persons utterly incompetent to attend to the dispensing of medicines. It is true that on opening a pharmacy, they are required to give notice to the board of health, yet this is a mere form, and does not involve any inspection by a proper authority to ascertain whether the pharmacy is suitably equipped or provided with a trained pharmaceutical chemist. Thus it happens that sometimes a women or even a child may be seen in charge of the drug shop, while the principal is absent for an hour or two. Even when the incompetent manager of the branch business is himself present, it is not uncommon for him to dispatch a boy by the back door, to some neighbouring skilled druggist's, to execute a prescription, while he, with pleasant words, craves the indulgence of his customer on account of the care and time requisite in order that his (?) dispenser may compound the difficult prescription. The use of patent medicines is common in South America. Physicians prescribe them to a large extent, so that fortunately, in view of the abuse just referred to, the keeper of a pharmacy can thereby escape with fewer blunders.

In order, however, to correct this evil, the Society of Pharmacy at Buenos Ayres had, at this meeting on the 21st of last March, prepared a petition, and transmitted the same to the assembly, in which it is requested that provision be made for a class of pharmacial assistants to be denominated "Dependientes Aprobados."

The petitioners request that it may be by legal enactment forbidden to carry on a pharmacy without either the personal attendance of the licensed pharmacist himself, or a "Dependiente." The latter are to pass an examination in:—

I. Reading and preparing two prescriptions.

II. Recognizing by their physical characters and determining the dose of four chemical products and four organic preparations.

III. Performing three simple operations in practical pharmacy. Those passing a favourable examination are to receive a certificate sealed with the society's seal.

Licentiates in pharmacy are those who, having passed a satisfactory examination before the Faculty of Medicine, are awarded a diploma, and authorized to establish themselves as druggists wherever in the republic they may find a promising opening.

To prepare applicants for the examination, there is a course of study in the College of Medicine, especially intended for pharmacial students, and extending over a term of two years. To enter upon this course, certificates must be brought of having completed studies in grammar, geography, history, mathematics (higher and elementary), literature, and one modern language, Latin, or Greek, moral and mental philosophy, physics, organic, inorganic and analytical chemistry and natural history. The three last mentioned studies must have been pursued at a national college.

At the present time there are but two chairs of the "College of Medicine and Pharmacy" at Buenos Ayres, especially devoted to giving instructions to students in pharmacy. These are the professorships of botany and of pharmacology. Such other branches as they pursue, are studied in common with the medical students.

Besides these provisions for instructions to students of pharmacy at the "College of Medicine and Pharmacy," the faculty also examine and award licences to those who may have pursued similar studies elsewhere. Foreigners who may have graduated at colleges of pharmacy in other countries, are not exempt from this examination, if the said colleges are not connected with regularly established universities. The examination is both a theoretical and a practical one. Theoretical in physics, chemistry, natural history and pharmacology, and practical in the latter branch, including the making of eight pharmacal preparations. The fees are about fifty dollars.

Inspection of Pharmacies.—This occurs but once each year, and is attended to by the board of health, at least two members of which are always pharmacists. It is aimed at being such an official examination as is usual in most of the continental states of Europe; it can, however, hardly be considered as yielding altogether satisfactory results, from causes all of which I cannot here enumerate.

One of the chief difficulties is that the inspection does not occur sufficiently frequently. Often directly after the official examination has taken place, parties will open pharmacies and carry them on in a manner altogether to the reproach of the profession and prejudice of the community, resting perfectly secure from investigation for the period of a year. Then they will properly equip their establishments and reform their methods of doing business in time for the duly announced annual inspection, only to go on in a like illegal manner after the official visit has taken place.

Again, it is beyond all doubt an error, for reasons that are apparent, to have a board of inspection consisting almost entirely of medical men. Doubtless special experience in pharmaceutical matters should be as highly esteemed in the Argentine Republic as elsewhere.

It is also a faulty method to announce the time of inspection a long period in advance. Abundant opportunity is thus given to the unscrupulous druggist to duly "set his house in order," that the periodical visitation may not disastrously affect him.

In general I noticed that the honourable and thoroughly competent pharmacists in Buenos Ayres entertained grave suspicions of the value of the inspection, from the superficial and inadequate manner of its performance.

"*La Sociedad de Farmacia Argentina,*" or "Argentine Society of Pharmacy," located at Buenos Ayres, is the national pharmaceutical organization of the profession in the republic. It has done much during the twenty years of its existence to elevate the profession, and is still very useful. There are at present fifty-four active and about forty corresponding and honorary members. The president is the distinguished chemist and pharmacist, Professor Kyle, originally from Scotland. The society has a library and collection located in a central position, at the corner of two principal streets in Buenos Ayres. Three meetings of the society are held monthly, one for business, and two for the discussion of scientific and professional questions.

Each year prizes are offered for the best memoir or research in chemico-pharmacy. The society appoints a committee of three of its members to examine the manuscripts and report the successful competitor.

One feature of the society is peculiar. With the fees, dues and fines, there has now been accumulated a fund, from which, on the death of an active member, five per cent. is paid to family of deceased. The capital now amounts to nearly 10,000 dols. The initation fee is 12·00 dols.; the monthly fee is 1·20 dols. There is, thus, life insurance connected with the privileges of membership.

"Revista Farmaceutica," the title of the journal of the society, its official organ, and now in the eighteenth year of publication, is a monthly large octavo of forty-eight pages. It is edited by a committee of five, and furnished gratis to all members. Besides Argentine pharmaceutical news, it contains the proceedings of the society and various scientific articles and translations.

Miscellaneous Items.—There is no Argentine Pharmacopœia, but those of various European nations are used, usually according to the nationality of the respective physician prescribing. When no particular one is specified, that of the French (Codex Français) is used.

The drug stores of the republic resemble, as to their fitting, more those of the continent of Europe than any others I have seen. They are mostly small and, while as a rule neatly furnished, there is no attempt at display. The long list of extraneous wares kept at druggists in England and in the United States is not found, nor are mineral waters or soda ever kept on draught. There is a printed tariff of retail prices, which all respectable druggists adhere to. It is considerably higher than usual in the United States.

The Argentine Republic has provided at least one work on a pharmacal subject which, in Spanish, is perhaps one of the best. I refer to Carlos Murray's 'Pharmacy and Pharmacognosy,' now passed to a second edition.

Pharmacy in Chili is not altogether in as satisfactory condition as in the Argentine Republic, though the general features are much as in the latter country. I will only allude to some that differ considerably.

The profession is largely in the hands of foreigners, few of whom are Italians. English, French, and German, particularly the latter, have most of the better shops. The government now appears to have entered upon the policy of restricting the number of foreigners in the business, and of stimulating the natives to secure its control. Therefore of late years the examination in the case of foreigners has been exceedingly severe, more so, I should say, than in any other country of the world, if the representations made by some who have passed the ordeal can be relied upon. In one case the chemical examination alone involved six weeks of laboratory work as the practical portion of the examination. It was required to find out the composition, qualitative and quantitative, of specimens of paraffin, peat, and a mineral water. No amount of experience in other lands or diplomas of foreign countries can cause this examination to be lightened. For natives, or others, a course of two years is provided in the University of Santiago, but most of the studies are such as pertain to a general education, and those which are specifically pharmacal, I am informed, by competent judges, are not very thoroughly taught. Discipline is said to be lax, and superficiality in scholarship the rule. The examination at the close of each year does not compare in severity to that the graduate of a foreign school of pharmacy would be subjected to on seeking admission to the ranks of the profession in Chili.

There is a small society and journal of pharmacy at Santiago, neither of which exert very commanding influence.

What I have said regarding the character of the places of business in the Argentine Republic will apply equally well to Chili. In the large cities a certain number of druggists, as indicated by the Intendente, must remain entirely open each night for a week; all others may close completely by ten o'clock. Another set must remain open the following week, until the round is completed. In a population of forty thousand only two druggists, as a rule, would form the night contingent for one week. Retail prices are not uniform, and are very high. Chili is materially the most prosperous of the South American republics, though one of the youngest. It is not unlikely that the condition of pharmacy will steadily improve, as nearly all material, social and intellectual relations are constantly doing in this enterprising republic.

Pharmacy in Uruguay.—This smallest of South American republics—having a population only equal to the city of Chicago—hardly requires a special reference. The general character of pharmacy is as in the neighbouring Argentine Republic. There is a course for pharmacists in the University at Montevideo, though hardly an adequate one.

Uruguay has no society of pharmacists or journal devoted to pharmacy. The country is without any indigenous workers in any department of science, pharmacy included. The political disorder prevalent is not favourable thereto.

Pharmacy in Brazil is to a considerable extent in the hands of foreigners in the larger cities, but elsewhere there are few others than natives engaged in the business. Patent medicines form the principal bulk of the stock kept by a Brazilian druggist, chiefly French, English and American. Many nostrums that have had their day in the United States, also some that are little known with us, though made here, are enjoying a very great popularity in Brazil. These patent medicines are so largely prescribed by the physicians of the country that the compounding of medicines, or regular prescription work, forms comparatively but a small share of the pharmacist's ordinary duties. In short, he is in the main but the retailer of packages of medicines, put up ready for the patient's use by the foreign manufacturer, and supplied at wholesale by the importing house at Rio Janeiro.

There is no national Pharmacopœia, but those of various European nationalities are used, guided generally by the preference of the respective physicians. The weights and measures employed are those of the metric system.

It is not uncommon for a physician to have an interest in the profits of the pharmacist to whom he directs his patient, a practice which I believe is not altogether unknown in the United States.

The drug stores in Brazil resemble, as to their fitting up and general appearance, more nearly those of continental Europe than they do those of this country. Their fixtures are, to a large extent, supplied from France and Germany. The miscellaneous and *extraneous* articles usually found in a drug store in the United States are not found at the druggists' of Brazil, except to a comparatively very limited extent.

The display and elegance of the leading drug establishments in our large cities is nowhere equalled in Brazil, any more than is the case in the various countries of Europe.

Graduates in pharmacy in foreign countries are permitted to establish themselves as druggists in Brazil, upon satisfactory evidence of their having completed a pharmaceutical course of study. If they have not graduated at a school of pharmacy connected with some *university* they are, however, usually required to pass a rather detailed examination.

Many of the natives who are pharmacists have acquired their knowledge of the profession entirely of other druggists, and been admitted to practice on examination by the board of examiners provided for that purpose at Rio Janeiro.

The Faculty of Medicine, however, at Rio Janeiro and at Bahia, provides a special course in pharmacy, in which the following subjects are taught: Physics, chemistry, mineralogy, botany, materia medica, and pharmacy.

The students have the advantages offered by a chemical laboratory, physical cabinet, natural history collections, and a practical dispensatory.

At the Rio Janeiro there were, in 1874, 113 students of pharmacy, and 95 at Bahia. In the same year there graduated, at Rio, 32; at Bahia 64. There is a matriculation examination for the students in pharmacy, in the following branches: Arithmetic, geometry, and French.

There is in Brazil the following pharmaceutical societies: the Pharmaceutical Institute of Rio Janeiro, the Brazilian Pharmaceutical Society, and the Pharmaceutical Academico Athenum.

The first-mentioned carries on, with the assistance of the government, a so-called "School of Humanities," which appears a sort of preparatory institution for pharmacists. This society also publishes a review entitled the "Tribuna Pharmaceutica."

The Brazilian Pharmaceutica publishes a monthly periodical, denominated "Abelha" or "The Bee."

All the three societies above mentioned co-operate in the formation and revision of the official course of study insisted upon by the Imperial government for those contemplating the profession of pharmacy.

SATURDAY, MARCH 10, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE PUBLIC FUNCTIONS OF THE PHARMACEUTICAL SOCIETY.

THE luxury of indulging in law proceedings is proverbially expensive, and often one of the results most obvious to a litigant is that he has contributed to the prosperity of the gentlemen of the long robe. We do not suppose it would add much to his satisfaction even if to this privilege were added that of raising simultaneously a contribution to Her Majesty's Treasury. Such, however, is the position from which we are able now to congratulate the Pharmaceutical Society upon its escape. This will appear from the following statement of facts.

In performing the duty imposed upon the Pharmaceutical Society by Parliament, of carrying out in the interests of the public the provisions of the Pharmacy Act, it has become necessary on various occasions to institute legal proceedings against offenders. Almost invariably when these cases have been carried to a hearing a penalty has been imposed, and this has exercised a certain amount of deterrent influence. So far, such a result has been satisfactory, but it has nearly always involved a cost to the Society far exceeding both the penalty imposed upon the offender and the costs allowed, so that the expense of such proceedings for the protection of the public have in fact been to a great extent borne by that portion of the trade which constitutes the Pharmaceutical Society. It might therefore have reasonably been assumed that the penalties recovered under the Act would be left in the hands of the Society as partial reimbursement of its expenses in carrying out a public duty.

Such an assumption, however, would have been unwarranted, as was evidenced by two penalties recovered in Glasgow being claimed by the Queen's Remembrancer in Scotland last October. It became necessary therefore to make a formal application to the Commissioners of Her Majesty's Treasury,—who, according to the 14th section of the Act of 1852 and the 15th section of the Act of 1868 are the authorities to decide to whom the penalties shall be paid,—that they would direct that the penalties should be retained by the Society. Somewhat unexpectedly this application met with a prompt refusal, accompanied by an order to pay over to Her Majesty's Receiver of Fines all penalties recovered under the Acts since they were passed. This communication was considered by the Council at its meeting in November last, when a deputation was appointed to wait upon the Commissioners of Her Majesty's Treasury with a view to obtain a more favourable decision.

After an interval of nearly three months, an appointment was made for an interview, and the deputation laid before the Secretary to the Treasury the reasons why the Council thought the Society should be allowed to retain the penalties. It is satisfactory to find that upon reconsideration these reasons were deemed sufficient by the Treasury, and that in a letter which was read at the meeting of the Council on Wednesday last, and which will be found in another page, the Commissioners of the Treasury cancel the previous order to pay into the Exchequer the fines in question.

We suppose the original refusal was based upon a very natural and proper hesitancy on the part of the Government to allow, even in appearance, the levying of penalties in the name of Her Majesty by a body over whose proceedings it has but little control. Still, so long as the Pharmaceutical Society is thought worthy of its expensive trust of watching over the public safety,—for it must not be forgotten that the Pharmacy Acts though incidentally beneficial to chemists and druggists have their primary *raison d'être* in the welfare of the public,—so long it cannot logically be asserted that it is unworthy of being entrusted with the disposal of the penalties.

But we are inclined to think that it would be a great gain to the Pharmaceutical Society should the day ever arrive when, by the appointment of a Public Prosecutor, it is relieved of this portion of its duties; for it is quite possible that even while performing them faithfully the Society's influence is injured in other directions. Thus, amongst chemists and druggists themselves, opinions will vary that the Society is doing too much or too little, just as individuals stand in relation to particular cases; whilst by those leaders of public opinion, the writers in the daily press, the strength of their condemnation is often in direct ratio with their ignorance of the subject under discussion. It is no uncommon occurrence for them to call for the enforcement of a law that never existed outside of their own imaginations, and to give the schedule of poisons an elasticity never dreamt of by Parliament.

We need go no further than the proceedings that culminated at the Old Bailey during the present week for an illustration of our remark. The appearance of a prisoner at Bow Street charged with personation at the Preliminary examination let loose a flood of sensational generalities upon the facilities that existed for the perpetration of such an offence, and the possible influence upon the civil service. Intermixed with these have been several statements calculated to produce a prejudicial influence upon the public mind. Thus the *Pall Mall Gazette*, with its lofty style of general censuring which it appears to think a necessity when a "gentleman is writing for gentlemen," remarks of the Pharmaceutical Society, that it appears to be unusually lax in its method of administering the functions entrusted to it by law, though this is *à propos* of nothing more pertinent than that probably similar frauds to that discovered by it are suffered undetected by other bodies. We take leave to say that, even in the present days of loose writing, such a charge, made without a tittle of evidence to support it, is itself "unusually lax," and probably would not have been made had the writer been possessed of adequate knowledge as to what are the functions entrusted to the Society by law or how they are administered. The *Standard*, too, in its wisdom, could not see the necessity of requiring from a man who was acquainted with drugs a proof of his knowledge of Latin and arithmetic, although the writer's life has possibly before now depended upon his chemist's ability to read correctly the directions and apportion the doses in his physician's prescription. We regret to note that something of the same sort of feeling tinged the remarks of the learned judge before whom the case came, and influenced his judgment. Even if the Preliminary examination were the mere literary exercise it was assumed to be, and not a portion of the test of the candidate's fitness for his business, we submit that the essence of the offence was in evading it, and that the fact of one of the offenders having passed the Minor examination afterwards was an accident of the case, which neither increased nor mitigated his culpability, and had absolutely nothing to do with his accomplice. The result was that the Society appeared to ask, through its representatives, for a punishment more than commensurate with the offence, and furnished a fresh reason for using great circumspection before exercising the functions that we hope one day to see committed to a public functionary.

In conclusion, we would remark, that in the prosecutions at Salford for the alleged sale of adulterated balsam of copaiba, there is another proof that the final result is not always the measure of desert in respect to legal proceedings, it having fallen to the lot of the Trade Association to appear in the only case of the three in which a fine was inflicted.

THE QUALIFICATIONS OF PUBLIC ANALYSTS.

THE proceedings which took place on Thursday last, at the Town Hall at Salford, a brief account of which will be found in another part of this Journal, are calculated to create feelings of mistrust and alarm among many of our readers. Three druggists, Messrs. WHITAKER, HALL, and HOLT, had been summoned before the magistrates on a charge of selling adulterated balsam of copaiba to the inspector under the Adulteration of Food and Drugs Act. The cases had been once adjourned by desire of the local authorities; chemists in Manchester, Liverpool, and London had been engaged on behalf of the defendants to analyse the suspected samples, and much interest was excited among the members of the trade—an interest comparable to that which was created by the sweet spirit of nitre and the scammony cases which occurred in London some time ago. In two of the cases the defence was undertaken and chemical evidence provided by the wholesale houses who had supplied the balsam, Mr. SIEBOLD of Manchester having been employed by Messrs. EVANS and SONS of Liverpool in WHITAKER'S case, and Professor REDWOOD by Messrs. HEARON, SQUIRE and FRANCIS of London, in HALL'S case, while Professor ATTFIELD, acting for the Chemists and Druggists' Trade Association, was prepared to give evidence if required. These chemists had arrived at the conclusion that WHITAKER'S and HALL'S samples were free from any adulteration, but that HOLT'S sample had been adulterated by the addition of a small quantity of some fixed oil.

In only one of the defended cases was evidence given, for after hearing the defence in the first of these cases the magistrate immediately dismissed it with costs, and a similar result was accepted without evidence in the other case. These results, however, were due to the nature of the evidence produced, at considerable cost, for the defence.

The remarkable feature of the proceedings consisted in the evidence given by the public analyst, Mr. J. CARTER BELL, who represented WHITAKER'S sample as adulterated with 35 per cent., and HALL'S with 28 per cent. of some foreign volatile oil, while he alleged that HOLT'S sample contained about 80 per cent. of a fixed oil. He had arrived at these results by the application of tests which have long been shown to be fallacious, and had used the tests for a purpose for which they were never intended and were wholly inapplicable. In fact it was evident that he was entirely ignorant of the means of testing balsam of copaiba, and hence the absurd conclusions at which he arrived.

Now, it is really a very serious consideration that tradesmen should be subject to loss of character, and consequent ruin, through the employment as public analysts of men who, without possessing any sufficient acquaintance with subjects they undertake to investigate, rashly jump at conclusions, and condemn as adulterated, articles which, when examined by competent chemists, are found to be perfectly genuine and good.

ACCLIMATIZATION IN QUEENSLAND.

AMONGST the successful experiments in acclimatization mentioned in the last report on the Brisbane Botanical Gardens, plants of the breakfast table are well represented. No less than forty varieties of sugar cane are cultivated in the gardens, and nearly a hundred thousand plants were distributed to colonists during the year. The ordinary coffee plant (*Coffea arabica*) is reported healthy, and thirty acres are to be put under crop during the forthcoming season. Seeds of the Liberian coffee plant (*Coffea liberica*) also have germinated, and healthy plants have been distributed. As for tea, all that appears to be required is skilled labour for the manufacture of the crop at a reasonable rate, many parts of the colony having proved to be adapted for the production of superior varieties. The Paraguay tea plant (*Ilex paraguayensis*) is also flourishing. Amongst other important economic plants introduced to the gardens during the year are the balsam of tolu plant (*Myroxylon toluifera*), the Sumatra and Penang rubber plant (*Urceola elastica*), and the Siam gamboge (*Garcinia morella*, var. *pedicellata*).

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL.

Wednesday, March 7, 1877.

MR. JOHN WILLIAMS, PRESIDENT.

MR WILLIAM DAWSON SAVAGE, VICE-PRESIDENT.

Present — Messrs. Atherton, Atkins, Betty, Bottle, Cracknell, Greenish, Hampson, Hanbury, Hills, Mackay, Owen, Rimmington, Robbins, Sandford, Schacht, and Shaw.

The minutes of the previous meeting were read and confirmed.

PERSONATION AT THE PRELIMINARY EXAMINATION.

The PRESIDENT drew attention to the case of personation at a Preliminary examination, in which the solicitor had been instructed to take proceedings, the result of which appeared in the *Times* that morning. This case is reported at p. 745 of this Journal.

APPLICATION OF PENALTIES RECOVERED UNDER THE PHARMACY ACT.

The SECRETARY read the following letter with regard to the application of penalties recovered under the Pharmacy Act:—

"Treasury Chambers,
"21 Feb. 1877.

"Gentlemen,—I am directed by the Lords Commissioners of Her Majesty's Treasury to acquaint you that upon consideration of the arguments brought forward by the deputation from your body which recently waited upon the Financial Secretary to this Board, with reference to the disposal of the penalties imposed under the Acts of 15 and 16 Vict. c. 56, and 31 and 32 Vict. c. 121, and upon further reference to the provisions of the 12th and 14th sections of the former, and the 15th sertion of the latter Act, my Lords are not prepared to give any directions for the payment to the Exchequer of the penalties referred to in the letter from the Registrar to the Society of 4th Oct. last.

"You are therefore at liberty to retain those penalties which my Lords understand to have been imposed under the sections above referred to, and you may regard the instructions to pay them over to the Receiver of Fines, contained in the letter from this Board of 13th October, as cancelled.

"I am, Gentlemen,
"Your obedient Servant,
"William Law."

"The Pharmaceutical Society of Great Britain,
"17, Bloomsbury Square, London, W.C."

Mr. SHAW remarked that the Society expended a great deal of money in carrying out the law, and it was only just that the penalties recovered should be retained by it. Last year the sum of £250 was spent in law expenses, and the previous year £385.

The SECRETARY said he feared that the recent prosecution for personation would be very costly.

The following, being duly registered as Pharmaceutical Chemists, were respectively granted a Diploma stamped with the Seal of Society:—

Babb, James.
Glover, William Kensit.
Jones, George Marsh.
Littlewood, John Oscroft.
Peat, Joseph.

ELECTIONS.

MEMBERS.

Pharmaceutical Chemists.

Campbell, Henry ....Redcar.
Farmer, Charles Adolphe ......London.
Jones, George Marsh ....London.
Peat, Joseph ... .London.

Chemists and Druggists.

David, Samuel Sinclair ....Laugharne.
Hunter, John Wilson ....Gateshead.

Mr. James King Haworth, an Associate of the Society before July, 1842, was elected a Member.

ASSOCIATES IN BUSINESS.

The following, having passed their respective examinations, being in business on their own account, and having tendered their subscriptions for the current year, were elected "Associates in Business" of the Society:—

Minor.

Batchelor, Alfred Ernest ......Fareham.
Cooper, Herbert Hudson.........London.
Fowke, Robert Main ....Lewisham.
Gooseman, John Brocklesby ...Great Grimsby.
Humphries, Edgar ....Garston.
Lawson, William ....Bellshill.
Mackenzie, Charles Anderson...Hastings.
Mackenzie, George Grant ......Alness.
Marsh, Edward Robert ....London.
Moore, George Brass ....Southport.
Righton, James ....Southport.
Saunders, Arthur ....Walthamstow.
Sykes, Henry ....Huddersfield.
Veitch, Andrew..... ....Castle Douglas.
Vince, James ....Lancaster.

Modified.

Edwards, Thomas Roberts......Devizes.
Hill, John ....Reading.
Oates, Edward Brooke ....Dewsbury.
Spurgeon, Frederick John ......Ipswich.

ASSOCIATES.

The following, having passed their respective examinations and tendered (or paid as "Apprentices or Students") their subscriptions for the current year, were elected "Associates" of the Society:—

Minor.

Allsworth, Norman ....Havant.
Ashburner, Isaac ....Broughton-in-Furness.
Avison, David ....Wakefield.
Bayston, George Coryndon ....Guildford.
Bond, Alfred.........................Fallowfield.
Bullen, George William ....Newark.
Campbell, Charles..................Hull.
Challice, Swann Ripsher ....London.
Crook, Charles William Wallace Plymouth.
Dixon, Herbert......................Retford.
Edwards, Frederick William ...Bradford.
Fletcher, Redfern ....Newcastle-on-Tyne.
Francis, Rawson Parke ....Diss.
Gibbs, John ....Worcester.
Green, George ....Horncastle.
Gutheridge, George Frederick...Falmouth.
Hall, Edward......... .. ..Norwich.
Hume, John William David ...Stokesley.
Keith, Alexander Reid ....Arbroath.
Lees, David ....St. Andrews.
Matthews, James Wavell ......London.
Peirson, Henry ....Banbury.
Rickarby, Arthur George.........Bromley.
Russon, Samuel Tonks............Birmingham.
Shenstone, James Chapman......Colchester.
Shilton, James ....Sutton Coldfield.
Southee, William Jennings.......London.
Squire, Frederick John Cripps...Plymouth.
Stewart, Duncan ....Crieff.
Wastie, Francis, jun. ....London.
Weatherley, Richard John ......Teignmouth.

Modified.

Gall, Frederic ....Devizes.
Lloyd, Thomas Edwin ....London.
North, Thomas Henry ....Hull.

APPRENTICES OR STUDENTS.

The following, having passed the Preliminary examination and tendered their subscriptions for the current year, were elected "Apprentices or Students" of the Society :—

Aston, Walter ....Tarporley.
Beck, Albert Neve ....St. Leonards.
Bell, Robert R. ....Liverpool.
Bosher, Alexander ....London.
Cooper, Thomas Edward ....Wellington.
Evans, Thomas Fryer .... Manchester.
Goss, Samuel Howard ....Barnstaple.
Greenhill, Samuel Osborne ......Colchester.
Griffiths, John Moore ....Birkenhead.
Heath, Robert Philip ....Norwich.
Herbert, George ....Shap.
Higgs, Alfred ....London.
Hoare, William Parker ....Cirencester.
Hoddinott, Francis Frederick...Chipping Campden.
Hoult, Joseph Emanuel ....West Bromwich.
Inglis, William Keiller ....Ashton-under-Lyne.
Jones, Hugh ....Abergele.
Keeling, John Henry ....Hackney.
Kent, Benjamin John ....Boston.
Notcutt, William Brighty ......London.
Patterson, James ....Landport.
Shields, William ....Belfast.
Shine, Alfred J. ....London.
Smith, William Thomas ....Bath.
Stacey, Frederick Charles ......London.
Swift, Philip Dickerson ....Spalding.
Todd, Matthew James..........Sunderland.
Watts, Arthur Rugg ....Shaftesbury.
Williams, Samuel Roskelly ......Devonport.
Williams, William Jesse ....Crickhowell.
Wilson, William, Joseph.. ......Oxford.

The following names were restored to the Register of Chemists and Druggists:—

Challice, Swann Ripsher, 79, Tachbrook St., Pimlico.
White, Fitzherbert, Birchfield Rd., Birmingham.

Several persons were restored to their former status in the Society upon payment of the current year's subscription and a fine.

Reports of Committees.

Finance.

The report of this Committee was read and adopted, and various accounts ordered to be paid.

Benevolent Fund.

The report of this Committee recommended that a grant of £20 be made to the widow of a late member.

The report was received and adopted.

Revised Regulations for the Benevolent Fund.

Mr. Shaw then moved.—

"That the Benevolent Fund Regulations now submitted be received and adopted with exception of the last one respecting the canvassing."

He said that the Committee had gone carefully over the regulations clause by clause, and made a few alteration, but as a whole the regulations now submitted were very similar to those he had before brought forward. The sub-committee had been divided in opinion with regard to the clause with reference to canvassing and he proposed, therefore, that that clause should be considered separately. He then stated briefly the nature of the alterations introduced, the principal one being that the names of persons recommended for election as Annuitants should be placed in a book, and a second selection made at the end of the year.

Mr. Sandford said the sub-committee had gone carefully through the regulations, and the alterations in regard to matters of principle were as follows:—At present the Council decided in June how many annuitants should be elected in October; now it was proposed to determine the number in October and elect in December. The next point was that if any one who had been a subscriber to the fund became a candidate for a pension, votes equivalent to the total amount of his contributions to the fund should be carried to his credit. That proposition was a novelty, and it was for the Council to say whether it agreed to it. A similar regulation was in operation in connection with the Royal Agricultural Benevolent Institute, and was reported to work well. Then, again, the votes of each unsuccessful candidate were at present carried forward for four years but no longer. There appeared to be no reason why there should be this limit, and it was now recommended that the votes should be carried forward to all future elections. Another important matter was an amplification of the clause providing for the forfeiture of an annuity in certain cases at the discretion of the Council.

Mr. Robbins suggested that the rules as now revised should be circulated amongst the members of the Council, and the decision deferred for another month.

Mr. Shaw said the regulations had been distributed a month previously.

Mr. Betty said the regulations had in fact been before the members of the Council for three months. The Committee was unanimous in favour of every alteration now recommended.

Mr. Schacht asked if the Committee had directed its attention to the verbal alterations, because it appeared to him that many were required. He should therefore support Mr. Robbins's suggestion.

Mr. Hampson objected to putting the decision off any longer.

Mr. Bottle objected to the alteration which proposed to carry forward the votes indefinitely instead of being limited to four years. The old rule had worked admirably, because every candidate who had been put on the list had ultimately been elected. To alter the rules so that the votes would accumulate *ad infinitum* would be setting up the minority against the majority, because any candidate, however objectionable he might be to a considerable number of voters, would be bound in the end to succeed.

Mr. Sandford said there never had been a candidate yet who had not got in in less than four elections.

The President remarked that the candidates were first selected by the Committee and approved by the Council, so that every one was supposed to be equally eligible.

Mr. Robbins said on the other hand the Council might see reason to change its opinion of a candidate, and if he did not succeed in four years it would indicate that there was something unworthy in him.

Mr. Sandford observed that the new regulations could not come into force until 1878.

Mr. Shaw thought there was nothing to prevent their being put in operation at once.

Mr. Schacht moved an amendment,—

"That the revised regulations be printed and circulated amongst the members of Council before they were finally adopted."

Mr. Robbins seconded the amendment.

Mr. Hanbury said it was necessary that the regulations should be as correct as possible in every way before they were made public, but he understood that the sub-committee had carefully revised them.

Mr. Betty said this had been done. He did not think the Council would have any cause to regret passing the regulations as now proposed, and it would seem unnecessary to delay the decision.

Mr. SCHACHT thereupon withdrew his amendment.

Mr. ROBBINS said he objected to alterations which were not improvements, and he saw no advantage in postponing the election to December, while it would have the effect of depriving the newly elected annuitants of their money until after Christmas. Some of the other alterations he approved of, having suggested them himself.

The PRESIDENT remarked that under the present system, those who subscribed between October and December got no votes until the following year, and the consequence was the fund got no subscriptions during that period.

The amended regulations were then put and carried unanimously.

Mr. SHAW then moved the insertion of the following paragraph at the end of the regulations:—

"The Council, having in view the interests of candidates for annuities on the Benevolent Fund, earnestly desire that no printed canvassing cards or circulars be sent to the Members, Associates, Donors, or Subscribers, by any of the candidates or their friends. The Council will give a full and impartial statement of the circumstances of each approved candidate, and will publish the same in the *Pharmaceutical Journal* during the four weeks previous to the election; and will also insert such statement in the voting papers sent to the voters."

He was sorry to find this was likely to meet with some opposition, for the more he considered it, the more he was convinced of the desirability of this clause being inserted, not merely as a recommendation, but, as one of the regulations.

Mr. ATKINS said in that case the form must be altered.

The PRESIDENT remarked that the only form in which the clause would have a chance of being adopted would be as a recommendation.

Mr. SHAW said he should not like to run the risk of failure, and would, therefore, simply move it as a recommendation, and he trusted the result would be an honourable observance of it by all parties. He proposed this in the interest of the poor candidates, whom it was very desirable to relieve from all needless expense. Looking back to the discussion on this subject a year ago he would endeavour to meet the objections then raised. The first was that it was impracticable; but he presumed that if the Council was entrusted with the management of this fund it was competent to it to make such regulations as would be deemed most in the interest of the candidates. It had been done in other institutions and he did not see why it should not be done here. In the Royal Albert Orphan Asylum no canvassing or trafficking in votes was allowed, and if it was proved to have taken place the candidate was disqualified.

Mr. OWEN said that was not a very successful charity.

Mr. SHAW said the same rule was carried out in the Merchant Seamen's Hospital and it had worked well. The next objection was that it would throw the election into the hands of the commercial travellers, but these gentlemen were very numerous, and he did not think they were likely to all choose the same candidates and procure votes for them. A much greater influence was exercised under the present system by the wholesale houses, and probably the commercial travellers would feel almost bound to support the candidates favoured by the houses they represented. He believed the Council would be glad to be relieved from the position in which it was now placed. During the past three years those who had been elected the first time their names were put on the list were those who had canvassed right and left; on the last occasion there were five candidates, of whom one only did not canvass, and all the others were elected, though the person shut out was in his opinion one of the most deserving. Then it was said that the adoption of this rule would take all the heart out of the fund, but he could not see the force of the objection. The recommendation applied to existing subscribers, and if any one was very anxious to get a candidate elected he would still subscribe, and ask his friends to help him. What he desired was that subscribers should not be interfered with; but if they voted at the solicitation of a friend, they voted not for the candidate but for their friend. Then it was said that the appeals made by the candidates induced people to subscribe, but it was not a right principle to go upon, to add to the subscription list at the expense of these poor people. The fear seemed also to be entertained that he was desirous of placing the elections in the hands of the Council, but nothing was further from his thoughts. It was also said he wanted to deprive the poor people of the privilege of canvassing. It was not much of a privilege to spend money which they could not afford; the Council ought rather to try to prevent them squandering their scanty means. One poor man had expended £5 or £6 in canvassing, and though he was elected he died a week previous to the election so that the money was entirely thrown away. If the name of his widow were placed on the list was she to go through the same course again? He would conclude his remarks by reading the following passages from the circular of the Charity Voting Reform Association which put the case very strongly and clearly:—

"1st. The circumstances of the candidates recommended by the subscribers should be investigated by the Committee, both as to their positive eligibility and relative urgency, special reference being had to the consideration whether the candidates have claims for support on friends or relatives prior to those upon public charity.

"2nd. Those candidates who are proved by investigation to be eligible should be arranged according to the strength and urgency of their claims, such moderate number only being included in the list as would be likely to be provided for within a reasonable time.

"4th. Trafficking in votes, and the use of canvassing cards and circulars, should be prohibited under pain of forfeiture of the candidate's claim.

"One important function of the Association, already employed with success, is to prevent, in the case of new charities, the introduction of the present system of election, or at least of its admitted abuses. And the Committee may here mention that 'the managing body of the Railway Servants' Orphanage having unreservedly adopted the suggestions of the Charity Voting Reform Association, have reported that their first election was carried on with perfect satisfaction to their subscribers, and without a penny of expense to any applicant.

"To release hundreds of poor toiling widows and other applicants from cruel and unnecessary labour in canvassing, as well as from heavy and useless expenditure of time and money; to spare poor maimed and crippled invalids a weary and painful hunt for hospital and other letters; to discourage that systematic and shameless habit of begging, which is the fruitful source of pauperism, begging-letter writing, and imposture; to cover rather than coarsely expose the domestic woes and wants of our less fortunate neighbours by not compelling them to parade their sorrows in thousands of printed cards and circulars; to try and ensure a measure of attention and justice to the candidates and their comparative claims, rather than to foster a desire to 'oblige friends' or gamble in votes; in fine, to help the most helpless and befriend the most friendless, are objects worth earnestly contending for, even against the most formidable opposition."

Mr. HANBURY seconded the motion as he believed the principle involved was a thoroughly sound one.

The VICE-PRESIDENT was very sorry that the benevolent object of Mr. Shaw was quite impracticable. If this recommendation were adopted it would not prevent canvassing, and the report of the very charity from which Mr. Shaw had quoted showed that it could not be done without.

Mr. HANBURY said that the proposition did not go so far as he could have wished, but he saw the Council was not prepared to go farther, and therefore he supported it, as being better than nothing. He had been a subscriber to the Infant Orphan Asylum from the commencement, and had never read an application from any candidate. A long paper with the names of parties was sent round, which was too long to read, and therefore he entrusted his votes to the Committee, who were by far the best judges, and with whom the election practically rested.

Mr. HAMPSON said this was a very serious matter and he hoped the motion would be carried. The object was to prevent an abuse of which all charities more or less complained, or rather to control it. The system of canvassing often led to the election of the least necessitous candidates, whilst the weakest always went to the wall. They frequently heard of cases in which the applicant was paralysed or confined to his bed, and, though the most in need, was thus prevented from using the means which others could employ and placed at a great disadvantage. He hoped that, in the spirit of the present times, of the Charity Organization Society, and of common sense, the Council would sanction this recommendation as the first step towards abolishing the system of canvassing.

Mr. ATKINS thought the matter had better remain as it was, because unless the practice were absolutely prohibited, the recommendation would make things worse. He should be glad if canvassing ceased, but there were two sides to the question, and both should be fairly looked at. Those who lived in the country did not know much about the London candidates and could only get their information from the cards, and as far as his information went the expense did not usually fall on the candidates themselves, but was undertaken by their friends.

Mr. ATHERTON said there ought either to be an entire prohibition or else no interference at all. Such a recommendation would simply act to the disadvantage of the conscientious candidate who attended to it.

Mr. OWEN said in his opinion if the Council wanted to get money into the Benevolent Fund it must not prevent the candidates asking for votes. Nothing had been so beneficial to the benevolent institutions of this country as this system, for every case excited a vast deal of interest and tended to bring in subscriptions.

Mr. BETTY thought the Council might consider what charity really was before voting upon this question, and he was sorry to say that the meaning of the word in modern English had become quite different to that of the old Latin. "Charity" came from *carus*, and meant giving something to one who was dear to you, and the charity which was kept alive by canvassing was not worthy of the name. Any charity which could only be kept up by this artificial excitement was not sound or permanent in its character. Imagine a gentleman who subscribed half-a-crown to this fund just before an election. He would receive from the different candidates say six cards which could not cost less than 9*d*., so that for a net expenditure of 1*s*. 9*d*. he would have the satisfaction of thinking what a charitable man he was, and if he were one who thought canvassing the very life of charity he would probably place the cards in his drawing room for all his friends to see what a reputation he had for benevolence. It was evident from the tone of public opinion that this system of electioneering and charity mongering was not destined to endure much longer. The great bane of the charity of this country was the manœuvring and tricks which were resorted to at the election of candidates at our public institutions, and he should like any one who supported this system to go to the London Tavern on an election day and see for himself what really was the life of charity in England. It was an organized system of buying and selling relief. The Council had now an opportunity of entering a very mild protest against it, which he hoped would be embraced. It could not hinder private individuals from seeing their friends on behalf of candidates, but it could make it known that public canvassing through the post office was discountenanced. It was the same thing in the end whether the candidate or his friends found the money, and he must say he never received one of these cards without a feeling of regret that the poor person who had sent it, and who perhaps had not had meat on his table for a week, should have been put to such a needless expense.

Mr. ROBBINS said there were at least three systems of conducting charities; one, that which the Charity Organization Society attacked, and he went very far with it, where a large number of candidates were put on the list, so that unless they bestirred themselves and spent money, they had hardly a chance. Another system was that of leaving the election in the hands of a committee, giving no voice to the subscribers, and that he also objected to, because it took the life blood out of a charity. In their own Society they adopted a medium course. The Council examined into every case, and was very careful that none should be put forward which was not a deserving case, and a larger number were not put on the list than could get in within a reasonable time. There had never yet been a candidate for this fund who did not get in within three years. The plan had worked well, and it would be a pity to change it.

Mr. SANDFORD said he held very strong views on this subject, and had therefore consulted several secretaries and active members of different institutions, and found every one of them was of opinion that if the proposition of the Charity Organization Society were carried out, the charities themselves would fail. Mr. Betty intimated that charity was nothing unless arising from a proper motive, but he (Mr. Sandford) did not see that they were to judge other men's motives, they had simply to apply the funds placed at their disposal in the best possible way. These poor people did not, as Mr. Shaw said, pay their money to bring in subscribers; they made their case known to their friends by the best means in their power, and their friends subscribed in order to assist them. If they were not allowed to send round the cards how were their cases to be made known? Mr. Hanbury had told them that the list of cases he received was too long to read, but no doubt when the cards came before him singly he read them, and attended to the contents. It was very painful, no doubt, to receive these cards time after time, but he certainly did not consider when he received them that he had a portion of his subscription returned to him, as Mr. Betty intimated.

Mr. MACKAY could not vote for this recommendation, because in such a case as this he considered half measures worse than none. If the Council liked to put on the rules a distinct prohibition, that was one thing; but with this recommendation only it could not be said that a candidate was doing wrong in canvassing, and therefore the proposition had much better be negatived.

The PRESIDENT having spoken to the same effect,

Mr. SCHACHT said he wished to raise his voice distinctly in favour of canvassing. An expression he had made use of on a former occasion had been referred to, and he was quite ready to repeat it, that to prohibit it would be to take the life out of the Benevolent Fund. If it ever came to handing over the whole power of election to a committee, as Mr. Hanbury's remarks seemed to suggest, it would be fatal to the whole scheme. Mr. Betty had rather lofty ideas as to the nature of charity, which if carried out would prevent him taking any part in the Benevolent Fund dinner. Their province was not to teach mankind christian charity, but to direct its exercise and administer the funds which it supplied them with.

Mr. SHAW, in reply, said he could not see any force in any of the objections which had been raised, and he felt more strongly than ever the desirability of the change. He hoped at some future time a positive rule would be made, but, in the meantime he believed this recommendation would be a step in the right direction.

On the motion being put it was negatived by 12 votes to 6.

Mr. SANDFORD then moved,—

"That the amended rules come into force on and after January 1, 1878."

This was seconded by the VICE-PRESIDENT.

Mr. SHAW moved as an amendment that they come into operation forthwith, but, on a division, the amendment was negatived, and the motion carried.

BENEVOLENT FUND DINNER.

The Committee appointed last month reported that it had held three meetings and that the following gentlemen had been added to it, viz.:—Messrs. Owen, Robbins, Greenish, Hanbury, Barron, Professor Attfield, Dr. Paul, Messrs. Hampson, Stacey and Carteighe. It had been decided by the Committee that the dinner should be held on Tuesday evening, May 15, at 6.30 p.m., at the Freemasons' Tavern. It had been moved by Mr. Owen that ladies be admitted to the dinner, but after full discussion the motion had been withdrawn. A sub-committee was also appointed to draw up and issue circulars and make further arrangements.

Mr. HAMPSON asked why it had been decided not to invite ladies.

Mr. OWEN said he was desirous of ladies being present, and had on some occasions attended dinners which were very successful where ladies were present. But he had found there was no chance of carrying the motion and therefore had withdrawn it.

Mr. ROBBINS said if necessary the reasons which had influenced the Committee could be given, but he thought there was no necessity to do so.

The report was then adopted unanimously.

The PRESIDENT said there was one question which had not been referred to in the report, and that was, Who should occupy the chair at the dinner? His view was, that some gentleman of eminence should be asked to preside, but some of the Committee thought he, as President, should occupy that position Under the circumstances he would ask the Vice-President to take the chair while the Council discussed the question, and he should be glad if he could be relieved from the responsibility.

The PRESIDENT having retired, several members of the Committee stated that it was the unanimous opinion of the Committee that Mr. Williams, as President, should preside at the dinner. A resolution to this effect was carried unanimously and communicated to the President on his returning to the room.

CONVERSAZIONE.

This Committee had held a meeting at which a letter from the Lords of the Committee of Council on Education had been read, stating that the South Kensington Museum would be placed at the disposal of the Society on the evening of the 16th of May, for the purpose of holding a Conversazione. The Committee had given the Secretary instructions as to the arrangements to be made and the invitations to be issued.

Mr. SCHACHT suggested that tickets should not be sent to members in London any more than to those in the country unless they were applied for.

Mr. HAMPSON said if every one were obliged to apply for a ticket the success of the meeting would be jeopardized.

Mr. BOTTLE, as a country member, asked Mr. Schacht to withdraw his proposal. It would throw a good deal of extra work on the office, and this year there would be a deal of work at the same time in connection with the Benevolent Fund dinner.

The PRESIDENT said that the reason invitations for the Conversazione had been sent to the London members and associates in business without application was that a very much larger proportion of them would be likely to attend the Conversazione than of those residing in the provinces.

Mr. MACKAY suggested that tickets should be sent to all members and associates in town and country.

This was agreed to, and the report as thus amended was adopted unanimously.

THE BRISTOL PHARMACEUTICAL ASSOCIATION.

Mr. SCHACHT stated that a formal application had been made by the Bristol Association for some assistance from the Society's funds, but it was not received in time to be considered this month. It would, therefore, come before the Council at its next meeting.

LAW AND PARLIAMENTARY.

This report included the report from the Solicitor as to the progress in various matters he had in hand. The Secretary had stated that he understood the summons against a Nottingham chemist and druggist for prescribing was returnable on the 13th inst. A pharmaceutical chemist had written to the Secretary, reporting that he had been summoned to serve on a coroner's jury, and in reply to his protest had been informed by the coroner that there were no exemptions whatever in the case of inquests. The Secretary had been instructed to send him a copy of the section of the Juries Act relating to exemption from jury service, The Secretary had also reported correspondence with several parties accused of breaches of the Pharmacy Act, and the result of the prosecution for personation as reported elsewhere.

Some discussion ensued as to the question raised in regard to service on coroners' juries.

Mr. ATKINS said in his neighbourhood pharmaceutical chemists were never summoned. The officer could only go by the jury list, and if a man was not on the list he could not be summoned.

Mr. SANDFORD said he had often heard that coroners' juries were subject to no exemption, and that the officer was not obliged to go by the jury list.

The report and recommendations of the Committee were received and adopted.

LIBRARY, MUSEUM, AND LABORATORY.

The Librarian had reported to this Committee that the average attendance in the library during the preceding month had been as follows:—Day, 23; evening, 10. Circulation of books, in town, 182; in the country, 32 to 20 places. The donation to the library of Smiles' 'Life of a Scotch Naturalist,' by Mr. T. H. Hills, had been reported. The purchase of books required to complete the set of Longman's Text-books of Science was recommended; also of the Catalogues of Food, etc., in the Bethnal Green Museum. The question of purchasing the first seven volumes of the *Berichte der Deutschen Chemischen Gesellschaft* was considered, but the President stated that he had some of the back numbers which he should be happy to present to the library, and he would try if he could not get the set completed.

Professor Attfield had reported 61 entries in his class since the commencement of the session, 46 being now at work.

Professor Redwood had reported defects in the ventilation in the room in the basement in which his specimens were kept. This matter was referred to the House Committee.

The Curator had reported the average attendance in the Museum to have been during the month, in the morning 16, evening 3. Also that the Hanbury Herbarium was now ready for inspection. A proof of part of the chemical portion of the catalogue was submitted, and the President and Mr. Greenish undertook to look through it.

The report was received and adopted.

Mr. GREENISH asked that a copy of the Journal should be sent regularly to the Royal Botanical Gardens, D'Urban, Natal. The Curator of that Museum had sent over several things which were very useful to the Society's Museum and would be glad to receive the Journal. He thought it very important that the Society should have, if possible, a correspondent in every colony.

The suggestion was unanimously agreed to.

House.

The report of this Committee stated that its attention had been called to offensive smells in various parts of the premises, and that a sub-committee had been appointed to make further investigations. The water supply was stated to be ample, and a ventilating shaft which had been placed in the library was found to be effective. Various other matters connected with the house arrangements had been attended to, and a sub-committee had subsequently met and made recommendations as to the means to be taken for remedying the defects complained of, for which an estimate was now presented.

The report was received and adopted.

The President reported that very good progress was being made with the refitting of the octagon laboratory, but he asked for a further vote of £5 to replace the old chemical stove by one suitable for warming the room.

This was agreed to.

The Chemists and Druggists' Trade Association.

The Secretary read the following letter which he had received from the Secretary to this Association in reply to the resolution of the Council passed at its last meeting:—

"Chemists and Druggists' Association,
"23, Burlington Chambers,
"New Street, Birmingham,
"February 19, 1877.

"The Secretary and Registrar,
"Pharmaceutical Society of Great Britain,
"17, Bloomsbury Square, London, W.C.,

"Sir,—I have to inform you that your letter of the 8th inst. was submitted to the Law Committee at its meeting on Friday last, the 16th inst., when the annexed resolution was passed.

"I am, Sir, yours faithfully,
"W. F. Haydon, Secretary."

Resolved:—"That the Secretary be directed to acknowledge the resolution passed by the Council of the Pharmaceutical Society at its meeting on the 7th inst., which clearly answers the question put by the Secretary of the Association in his letter of November 27th, 1876; and at the same time to inform the Council that the previous letters of this Committee have been misunderstood, as this Committee had no intention of forcing upon the Council any cases, but simply of supplying, as they stated, such evidence as the Council might deem necessary if the Council on its part was willing to make use of the same."

A letter was read from the Secretary of the College of Pharmacy, New York, expressing the thanks of the College for the donation of some back numbers and volumes of the *Pharmaceutical Journal*, and the current numbers.

Report of Examinations,
February, 1877.

ENGLAND AND WALES.

	Candidates. Examined.		Passed.		Failed.

PHARMACEUTICAL MEETING.

Wednesday, March 7, 1877.

MR. JOHN WILLIAMS, PRESIDENT, IN THE CHAIR.

The minutes of the previous meeting were read and confirmed.

The following donations to the library and museum were announced, and the thanks of the Society were voted to the donors:—

Library.—Smiles' 'Life of a Scotch Naturalist,' from Mr. T. Hyde Hills; 'Berichte der deutschen chemischen Gesellschaft zu Berlin,' 1874, and part of 1873, from Mr. J. Williams; 'Sur l'avantage qu'il y aurait à remplacer la quinine par la cinchonidine dans le traitement des fièvres intermittentes,' from M. Weddell (Author).

Museum.—Specimen of Spurious Pareira Brava, from Mr. Gutheridge; Specimens of liquid Sulphurous Anhydride, Trioxide of Nitrogen, and Tetroxide of Nitrogen, in hermetically sealed tubes; also Sulphuric Anhydride, pure Iodide of Potassium, and Ammonio-sulphate of Nickel, from Messrs Hopkin and Williams; Specimen of very fine Sagapenum, in the tear, from Messrs. Hearon, Squire, and Francis; Specimen of the Gum of Ægle Marmelos, from Mr. H. W. Pound; Fruits of *Pedalium murex*, from Mr. Martindale; Sumatra Benzoin, in the tear, from Mons. Chantre; Crystals of Native Borax from California, from Mr. Robottom.

Mr. Martindale said, with reference to a specimen of gokhru which was exhibited on the table, that a notice had appeared in 'The Practitioner' for last November, stating that the juice of this substance had been used as a diuretic. In India it had proved useful in the treatment of gonorrhœa and diseases of a like nature. It was also mentioned in the Pharmacopœia of India.

A New Source of Borax.

Dr. Paul said that he had to bring before the Society that evening a new source of borax. Most of those present in the room would be aware that during the last two or three years the price of borax had been very considerably reduced. Within that period it had fallen from about £70 or £80 a ton to about £35 or £40 a ton, and the circumstance to which this fact was due was the discovery of the new source of this material, to which he now desired to draw their attention. Hitherto the supply of borax had been derived almost entirely from Tuscany, being manufactured from the boracic acid obtained from the suffioni in that district. A small quantity had been imported from Thibet in the form of what was commonly know as tincal, which is a naturally crystallized biborate of soda, and this had been shipped to England through India. There had been also a small quantity produced from the soda lakes in Nevada, situated at the south western part of North America. Two of these salt lakes, called Teel's Marsh and Fish

Lake, had been for a considerable time sources of supply of borax, not so much for the European as the American market. These lakes had been worked for six or seven years; but the cost of land carriage had been too heavy to admit of the working being continued, and he believed that they were now abandoned. The particular source that he wished to call their attention to from which the borax now came was in California, close to the River Colorado. It was a large lake of the same character as the two that had been worked in Nevada, which appeared to be the remains of previous volcanic action. This particular lake was about fifteen miles in length and eight miles across. It was entirely dried up, but the whole area of the lake was occupied with beds of common salt, sodium sulphate, borate of soda and blue mud. The native borax was now being worked by two American companies, and immense quantities of it were being shipped over to this country. Borate of lime had also been found to be present with the borax, and had been brought over to this country. Mr. Robottom, who had discovered this lake, and who had been mainly intrumental in bringing it into the market, was present and would perhaps give an account of some of the various uses to which he proposed to apply it. He would, however, draw attention to one of the uses of borax, for the preservation of animal and vegetable substances, as illustrated by some specimens exhibited on the table. A flower had been preserved in a strong solution of borax, and retained its colour and characteristics. A fish had also been preserved for some months in the same manner and was now perfectly sweet.

Mr. Robottom said that his reason for bringing the subject forward was to endeavour to utilize the immense quantity of borax which existed in this deposit. He had no occasion to go into its uses for medicinal purposes, as to which those present were better able to speak than himself. Apart from this, however, it was desirable to bring borax into use in the laundry to supplant soda; for it was found to be one of the finest washing substances in the world. It could be used also with great advantage in starching and in the getting up of lace and fine linen. Woollen materials were washed by it better than by anything else. Soda turned wool quite yellow, while borax made it perfectly white. The same remark would apply to flannels, and the colours of prints and ribbons were not affected by it in any way. In the district where he resided there were thousands of rabbits, and the skins of these animals were there generally sold for a small sum—about one farthing; he had induced poor people to preserve these skins with a little borax, and then make them into small mats, the whole cost of which was only a few pence. These skins had been utilized to replace blankets, for which they were a very good and cheap substitute. Next, there was the preservation of meat, and in connection with this he would mention a circumstance which first led him to think of using borax for this purpose. The last time that he was at the lake, he was fixing some boundary stakes, when his attention was drawn to a brown object lying on the surface of the borax, which on inspection proved to be a dead horse. On that day the barometer stood at 110° in the shade, but upon examination the flesh of the horse was found to be quite fresh. Further, upon inquiry of the men how long the horse had been lying there, he was informed that it had dropped down dead on the borax six months previously, and had been lying there since. This suggested to him the idea of preserving the different things which were shown. Borax was also valuable for cleaning paint; and glass globes were so well cleaned by the borax, that he had saved a considerable quantity of gas by it. It would be found that by using it in tea, a considerable saving would be effected. His own tea bill, since using the borax, had been reduced by about half. Borax could also be made into soap. A young gentleman came to him a short time ago and said that he had been greatly troubled by having to take balsam of capivi, but that, upon putting a piece of borax into the mouth, it acted like magic and took all the flavour away. There was another thing. In Manchester and Liverpool, particularly in the back slums, he had seen people on Sunday mornings buying cow cabbages, which weighed fourteen or fifteen pounds each. The stems of these cabbages were not nice to eat, but a piece of borax about the size of a penny-piece, boiled with the cabbage, made the green stalks quite beautiful to eat. It was a remarkable circumstance that there were scattered over the lake pyramids of carbonate of soda, about four feet high and as thick as a man's body; and there must be some hundreds of thousands of tons of this carbonate. Below the blue mud of the lake there was three feet of borax combined with sulphate of soda. When this had been taken out and put into warm water, the sulphate was dissolved, and left the borax. He believed that there was no place in the world where solid borax was found like the specimens exhibited.

In reply to the President, Mr. Robottom stated that at the lake water had to be fetched every day from a distance of fourteen miles. The number of workmen employed there was fourteen, who were Chinamen. The labour was very little, and they were each paid 7*s.* a day. He (Mr. Robottom) thought that none but Chinamen would be able to do the work. It was a very disagreeable country to live in. There was not a woman within forty or fifty miles. The ground all around the lake was perfectly free from vegetation. It was a difficult matter to get things conveyed to this locality. Twopence halfpenny a pound had to be paid for carting the houses, boilers, vats, etc., from Los Angelos to the works. The borax was conveyed from the lake by the bullion waggons which came into that district.

Mr. Martindale thought that the discovery was a very valuable one, particularly as being a source of yielding boracic acid. This acid would in future come into much greater use in medicine than heretofore, especially as an antiseptic dressing, either in plain solution in water or made into the form of ointment. It was one of the best antiseptic dressings that had of late come into use for simple burns, and boracic acid kept the part from suppurating and getting into that disagreeable condition which would arise in the case of other dressings. This new means of cheapening borax would be of great service.

The President said that the uses of borax were almost unlimited, and the uses mentioned by Mr. Robottom were insignificant in comparison with the use of borax as a flux in the arts. If it could be procured in large quantities, as was likely to be the case, it would take the place of many other fluxes now in use; but the high price at which it had previously been sold had prevented its being used to any great extent. He did not think that the borax could ever be supplied in quantities too great to find a ready market. There was also another very abundant source of borax in the mineral, a specimen of which was exhibited on the table, and which he believed was borate of lime. As a mineral they must admire the specimen very much. He believed that it yielded about 75 per cent. of borax.

Mr. Umney said it could not be supposed that the borax which had been supplied in such large quantities to the English market for the last two or three years had all been supplied by the working of fourteen men. He expected that the mineral to which the Chairman had alluded had been the source of most of it.

Mr. Robottom said that the Nevada company had supplied large quantities, but the largest amount of it was now being forwarded from the lake of which they had been speaking.

Dr. Paul called attention to the fact that the borate of soda, as now produced was procured ready for use, while the borate of lime had to go through an expensive operation to convert it into borate of soda.

A vote of thanks was passed to Dr. Paul and Mr. Robottom for bringing the subject before the Society.

A paper was then read, entitled—

NOTES ON THE ACTION OF CHLORINE UPON A BEAM OF LIGHT AND ON THE PREPARATION OF LIQUID CHLORINE.

BY DR. A. SENIER AND MR. A. J. G. LOWE,

The paper is printed on p. 729.

The PRESIDENT remarked that the communication reflected great credit upon the authors of the paper, and proved how simple and easy some apparently difficult operations became when conducted with intelligence and in a business-like manner. He could have scarcely believed that the liquid chlorine could have been prepared so easily. The preparation of condensed gases was attracting a great deal of attention at the present time, and the paper was, therefore, of great interest on that account.

A vote of thanks was accorded to the authors of the paper, and the proceedings terminated.

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, March 1, 1877. Professor Abel, F.R.S., President in the chair. After the visitors had been announced and the minutes of the previous meeting read and confirmed, the names of Messrs. J. R. Young, S. S. Bell, W. Watson, and F. W. Toms, were read for the first time. Messrs. Edward Hunter, Frederick Charles Cresswell Hewett, William Terrill, Alexander Kinninmont, John Borland, W. Handsel Griffiths, and George A. C. Pearce were ballotted for and duly elected fellows after their names had been read the third time.

The President then read the list of officers and other members of council proposed for election at the anniversary meeting, and announced that there would be a special general meeting held afterwards, to take into consideration the proposals of the council relative to alterations in the bye-laws regarding associates, and in the form of obligation to be signed by fellows on admission. The Secretary also gave notice that those fellows who wished to be present at the Chemical Society's dinner at Willis's Rooms on the 20th March should at once send in their names to Mr. Hall at Burlington House.

The President then called on Professor Thorpe to give his lecture "On the Theory of the Bunsen Lamp." The speaker, after some preliminary remarks as to the great value of this lamp, both to the scientific chemist and in the arts, pointed out the origin of it at the time when Bunsen introduced coal-gas into his laboratory. Bunsen considered the contrivances which had been used in this country as unworthy of the fuel they had to burn, and bringing his own great inventive powers to bear on the subject, the bunsen lamp was the result, the original apparatus differing but little from that now generally in use. After a short description of the lamp, the mode by which the air is drawn in at the holes at the bottom and caused to mix with the gas was considered. This is due to the well-known fact that when a gas under pressure, issues from an orifice, it carries with it more or less of the circumjacent air, partly as the result of the expansion and partly as the result of its viscosity. This was experimentally illustrated by an ingenious adaptation of List's multiplying manometer, which, when connected with one of the holes at the base of a bunsen lamp, distinctly showed the rarefaction produced by the gas as it issued from the jet, despite its low pressure. The intermixture of the gas and air in the tube is greatly facilitated by the spreading out of the gas stream after leaving the jet, and the amount of air carried in varies of course with the size of the air holes, being in an ordinary burner from two to two and a half times that of the gas. An average lamp giving a flame 120 mm. high, burns about 80 litres of gas per hour, so that as much as 250 litres of mixed gases pass through the tube of the lamp in that period of time. In some modifications of the lamp, such as Wallace's, the proportion of air is very largely increased, but then it is necessary to resort to some such contrivance as a perforated cap to prevent the flame retreating down the tube and burning below, for from Mallard's observations on the maximum rapidity of the propagation of combustion, it is evident that the velocity of the current of mixed gases in the tube of the bunsen lamp would have to exceed that of the velocity of the propagation of combustion, in order that the flame should not retreat down the tube.

Having traced the progress of the mixture of air and gas up the tube, attention was directed to the flame itself, which is hollow and contains a large internal area of the uninflamed mixture, as it has been found that a mixture of gas with less than three and one-third times its volume of air will not burn; it is only therefore when it meets with an additional supply of oxygen from the surrounding air that combustion occurs. The composition of the gas in the uninflamed interior cone is not the same in every part however, as has been shown by Blockmann. The amount of hydrogen, of the hydrocarbons, and of oxygen diminishing, and that of the carbonic oxide, carbonic acid, and especially the aqueous vapour and nitrogen being largely increased, the latter being derived from the surrounding air. This was still more clearly shown in a table giving the amount of air mixed with 100 volumes of gas, both in the tube and at various distances above it. The cause of the rapid diminution in the proportion of hydrogen and the corresponding increase in aqueous vapour is to be sought for in the greater diffusive power of the gas, and the lower ignition point of a mixture of hydrogen with air.

If the supply of air be cut off from the air-holes at the bottom of the bunsen lamp, the flame becomes luminous, so that the non-luminosity of the flame is due to the air, and at first sight it would be imagined that it was due chiefly, if not entirely, to the oxygen in the air, since it is known that an admixture of air with coal gas greatly decreases its luminosity; the nitrogen, however, is concerned in the matter, for if instead of supplying air at the holes at the bottom of the lamp we supply nitrogen or even steam, the flame at once ceases to be luminous, showing that the oxygen of the air is not necessarily the true cause. Knapp has shown that any indifferent gas, as carbon dioxide or hydrochloric acid, will produce the same result. Frankland proved many years ago that a mixture of marsh gas and air which was almost destitute of illuminating power might be made to give a luminous flame by heating the gas to redness, and Weber has recently shown that the ordinary bunsen flame becomes luminous when the gas is previously heated. This fact was experimentally illustrated by means of a bunsen lamp with a platinum tube; when the latter was heated to redness by means of a blowpipe, the flame became luminous, as when the air supply is cut off from the holes at the base. The feeble luminosity of the bunsen flame would appear to be due to a variety of causes, such as the oxidation of luminiferous material, the action of the nitrogen and other diluting gases, and the withdrawal of heat by the indifferent gases such as nitrogen, carbon dioxide, and water vapour, for although the temperature of a flame of coal-gas mixed with air is higher than that of one of unmixed coal-gas it requires a still higher temperature in order to become luminous.

When the gas is lowered in the bunsen lamp and the flame becomes very small, it will be seen that it does not rest immediately upon the end of the tube, a fact due to two causes, namely, the cooling action of the tube, and to the velocity of ignition of the mixed gases being less than the rate at which they issue. When the flame is very small, it is well known that the least current of air causes the flame to retreat down the tube and ignite the gas at the jet below; this is due to an admixture of air causing the velocity of ignition of the mixed gases to become greater than the rate at which it passes upwards in the tube. When the flame burns at the bottom a very much smaller quantity of air passes into the tube, and the gas which issues at the top is entirely deprived of oxygen, and has, moreover, a disagreeable odour arising in part from the presence of acetylene formed by the imperfect combustion of some of the hydrocarbons present, the amount of carbon monoxide also is very largely increased. The pernicious effect of this partially burned gas is due to the acetylene and carbon monoxide thus formed.

The President, in thanking the Lecturer, remarked that it would have been difficult to select a subject having a more special interest for working chemists; he had brought before them facts with which many were only generally or very partially acquainted, and made them familiar by his explanation and admirable experimental illustrations. Of the points of interest in the theory of the bunsen lamp which had been mentioned, perhaps those bearing on the luminosity of flames were of the greatest interest at the present time when so much attention was being directed to the subject.

Dr. Frankland said that although he had not paid any special attention to the luminosity of the bunsen flame, it had been a point of special interest to him to ascertain the cause of the greater or less luminosity of flames under certain conditions. With regard to the effect of dilution on the luminosity of the bunsen flame it had been advanced that when gases containing oxygen had been employed, such as carbonic anhydride, they had given up their oxygen, but there could be no doubt that this was not the case when nitrogen was used. From his own experiments, it was evident that a comparatively slight elevation of temperature has a great effect on the luminosity of a flame which was just on the point of becoming luminous. He had resumed his researches on the luminosity of flame and might say that he had repeated the very important experiments of Heumann, whose details of results he had found to be most accurate. He might mention that the exceedingly luminous flame of phosphuretted hydrogen did not give the faintest shadow in bright sunlight, showing that no solid matter was present in it, but as to whether the luminosity of carbonaceous flames was due merely to the great density of the hydrocarbon vapours, or to solid particles of carbon, was a matter which must still be considered as *sub judice*. The two important points to be determined were, the presence or absence of polarized light in carbonaceous flames, and as to whether a flame whose luminosity was undoubtedly due to the presence of solid particles would behave in the same way under diminished pressure as hydrocarbon flames, such as that of a candle, etc.

Mr. Vernon Harcourt wished to ask the Lecturer whether the luminosity of the bunsen flame, when the tube was heated to redness, might not be due in part to the formation of tarry matters or of hydrocarbons containing a large proportion of carbon, as it was not possible that the mixture of gas and air could be passed through the red hot tube without undergoing considerable change.

Dr. Wright suggested that the effect of heating the tube was comparable to that produced by lighting the jet below.

Professor Thorpe replied that Heumann had very carefully examined into the matter, and had found that when the experiment was properly performed there was no deposit of tarry or carbonaceous matter in the tube. If a much longer platinum tube to the bunsen were employed and only the lower part heated so that the gases became cooled again before being burnt, the lamp gave a non-luminous flame, showing that the luminosity was chiefly due to the heating. In reply to a question put by Professor Foster, he said that when a cold body was introduced into the luminous flame soot was deposited on it.

The President, after a formal vote of thanks to the Lecturer, adjourned the meeting until Thursday, March 15, when the following communications will be read:— 1. "Note on a Method for Estimating Bismuth Volumetrically," by Mr. M. M. P. Muir; 2. "Note on on Gardenin," by Dr. J. Stenhouse and Mr. C. E. Groves; 3. "Preparation of Copper-Zinc Couples," by Dr. J. H. Gladstone and Mr. A. Tribe; 4. "On Chromium Pig Iron," by Mr. E. Riley.

Parliamentary and Law Proceedings.

The Personation at the Preliminary Examination.

At the Central Criminal Court, on Tuesday last, before the Common Sergeant, sitting in the Third Court, John Thomas Faulkner Colegrove, Andrew Ritchie Hunter, and John Hinks, pleaded "guilty" to an indictment charging Colegrove with procuring himself to be registered in the Pharmaceutical Society's Register of Apprentices by false representations, and Hinks and Hunter with aiding and abetting him in so doing, contrary to the provisions of the Pharmacy Act, 1868.

Mr. Straight and Mr. Horace Avory appeared for the prosecution; Hinks was represented by Mr. Besley, Colegrove by Mr. Grain, and Hunter by Mr. C. Mathews.

The counsel for the prosecution briefly recapitulated the circumstances of the charge against the defendants, the substance being that, upon the introduction of Hun ter Colegrove by Hinks, Hunter undertook for a sum of £10 to personate Colegrove in the first or Preliminary examination of the Pharmaceutical Society, and to pass it for him. This deceit was successfully accomplished, and Colegrove became thus qualified to go in for the second or Minor examination, which he, in his turn, properly passed for himself, and so became registered as a chemist and druggist. In conclusion, Mr. Straight suggested that, with the consent of the Court, the defendant Hinks might be bound over to appear for judgment if called upon, but with respect to Hunter and Colegrove he applied that the provisions of the Act might be put in force.

It was pleaded on the part of the prisoners that they had hitherto borne excellent characters, and that so far as Colegrove and Hunter were concerned, they had already suffered nearly ten days' imprisonment. It was also urged that under the 14th section of the Pharmacy Act, 1868, the offence was one which, if committed in Scotland, was punishable by fine or imprisonment.

The Common Serjeant, however, thought that the phrase in the section might be held to be merely indicative of the class under which such an offence was to be included. In such a case as that before him he would have preferred to inflict a fine. After the counsel for the defendants had all been heard, the Common Serjeant said that having regard to the peculiar circumstances— above all things to the fact that the examination passed by Hunter for Colegrove was not a matter relating to the pratical business of a chemist and druggist, in which, from passing his Minor examination since, Colegrove would seem to be well versed, he would, especially as it was the first prosecution of the kind, allow the prisoners to go out upon their own recognizances to come up for judgment when called upon. The proceedings had been very properly instituted by the Pharmaceutical Society, and would no doubt act as a warning.

Alleged Adulteration of Balsam of Copaiba.— Another Public Analyst's Blunders.

On Thursday, March 8, at the Town Hall, Salford, Messrs. Whittaker, Hall, and Holt, chemists and druggists, of Salford, Manchester, were summoned for selling adulterated balsam of copaiba.

Mr. J. Carter Bell, public analyst for the district, said that the sample purchased of Whittaker contained

35 per cent. of foreign oils. Cross-examined, he said that he had never analysed balsam of copaiba before. He had tested the sample by half a dozen or more processes. Pure balsam should be soluble in rectified spirit, should dissolve a fourth of its weight of carbonate of magnesia, and should give a clear liquid with solution of ammonia of 0·965 specific gravity, but the sample did not respond to either test. Thirty-five per cent remained insoluble when the sample was shaken up with the spirit and therefore 35 per cent. of foreign oil was present. The foreign oil was a volatile oil, not a fixed oil, but he could not say what volatile oil it was. He relied on this spirit test and on the magnesia test which roughly confirmed the quantitative result of the spirit test. The sample contained a total of 48 per cent. of volatile oil, of which 13 was natural and 35 added. Questioned as to whether pure balsam ever did contain so little as 13 per cent. or so of volatile oil, he said he did not know, nor did he know what volatile oil could be used in adulterating copaiba. He did not recognize any particular smell suggestive of any particular volative adulterant.

The Magistrate: As I said in the milk cases, Mr. Bell, I think you ought to tell us not only the percentage of adulterant, but, also, the nature of the adulterant. How would the purchaser be prejudiced in this case?

Mr. Bell: I do not know.

Re-examined: The sample might have contained more than 48 per cent. of volatile oil, for the 52 per cent. of resin remaining might partially have been formed from the oil during evaporation.

This was the case for the prosecution.

For the defence Mr. Louis Siebold was first called. He had received from the defendant the portion of the purchased balsam which had been sealed and handed back to the seller by the purchaser. He had separated its volatile oil, and by the specific gravity, boiling-point and smell pronounced it to be pure oil of copaiba. He had otherwise examined the sample and had found it to be pure balsam of copaiba. Turpentine was not present; for the boiling-point of the volatile oil was not low enough to indicate turpentine, and the products did not smell of turpentine. The rectified spirit test of purity on which Mr. Bell had relied was absolutely useless. The sample certainly was not all soluble in rectified spirit, but many pure balsams, notably those of Para, were not completely soluble in rectified spirit. The other test relied on, namely, the magnesia test was useless. He, also, had found that the sample did not dissolve all the magnesia, but that was because the proportion of acid resin in the balsam was too small, and the proportion of such acid in balsam varied naturally. There was no Gurjun oil in the sample; for petroleum ether dissolved it, which would not have happened if Gurjun oil had been there.

Cross-examined: Copaiba, if adulterated, is adulterated in Brazil. Occasionally it was adulterated by fixed oil. The sample was faintly fluorescent, but, according to Flückiger and Hanbury, pure balsam was occasionally faintly fluorescent. Pure balsam was sometimes soluble in rectified spirit, but more often only partially soluble.

Professor Redwood who, although not engaged in this case, was present to give evidence in Hall's case was by consent called to corroborate Mr. Siebold's evidence, with which he entirely agreed.

The Counsel for the defence said that other chemists and witnesses were in court, but he would not trouble them.

The Magistrate: I have no hesitation in at once dismissing the summons, with costs.

The summons against Mr. Hall, on the agreement of the Counsel for the prosecution, was also dismissed with costs, the Counsel for the defence stating that Mr. Squire, of Coleman Street, London, partner in the firm of wholesale druggists who supplied the defendant, was present and prepared with witnesses to defend the case.

In Holt's case, Mr. Glaisyer, Solicitor to the Chemists and Druggists' Defence Association, said his executive had instructed him to defend all three of these cases, and he had to acknowledge the courtesy of the Town Clerk, who had supplied him with sealed portions of some of the Inspector's samples. The defence of Whittaker had, however, been undertaken by his wholesale druggists, Messrs. Evans and Co., of Liverpool. He (Mr. Glaisyer) had forwarded the sample in Hall's case to Professor Attfield, who was present, and all preparations had been completed for defence of that case, but on the previous evening Mr. Hall had finally elected to be defended by his wholesale druggists, Messrs. Hearon, Squire and Francis. In the third case he had been informed by Professor Attfield that fixed oil was present, whereupon he had at once decided to withdraw from the defence of that case. He desired to make this statement in explanation of his application to the Town Clerk for the sealed samples, which of course were given to him on the understanding that he would defend. He begged to retire.

Mr. Bell then gave evidence to the effect that this sample was adulterated to the extent of eighty per cent. with fixed oil which appeared to be linseed oil.

A fine of £5 was then imposed, and costs allowed.

A Mysterious Death.

On Thursday evening Mr. Carter held an inquest at the Globe Tavern, Regent Street, Lambeth Walk, on the body of Honor Kipping, the child of an artisan, who is alleged to have died from the administration of some drug obtained from a Mrs. Coomber, a registered chemist, of 10, Chester Street, Kennington Road. Mrs. Kipping deposed that on Wednesday night the deceased was very ill, and apparently suffering from measles. Witness went to a Mrs. Coomber, stated the symptoms, received two bottles, one containing castor oil and the other a medicine of a purple colour. Mrs. Coomber gave instructions that the deceased should have a tablespoonful of the castor oil and after the lapse of an hour a tablespoonful of the medicine. Witness did as she was told; but, although the castor oil sent the child to sleep, the mixture had such an effect upon her that the witness could hardly hold her. About 8 o'clock the next morning the child died. James Kipping said he went to Mrs. Coomber and told her of the death. She at once said, "Run back, then, and fetch the stuff," and he did so, and handed her the bottle. She put it to her mouth and said "Lord bless my soul; it is a bad job, I can't do anything for you." She walked up and down the shop and got out of sight, and he suddenly heard the tinkling of glass. She then came forward and handed witness the bottle, saying, "It is no fault of yours or mine. If I could have seen the baby my partner would have given a certificate." Witness ran home, and upon looking at the bottle saw that the purple liquid had been poured away, and a light-coloured liquid substituted. The Coroner said the case had assumed a very serious aspect, and he therefore adjourned the inquest for a fortnight for an analysis of the contents of the child's stomach to be made.—*Times.*

The following journals have been received:—The 'British Medical Journal,' March 3; the 'Medical Times and Gazette,' March 3; the 'Lancet,' March 3; the 'London Medical Record,' March 3; 'Medical Press and Circular,' March 3; 'Nature,' March 3; 'Chemical News,' March 3; 'Gardeners' Chronicle, March 3; the 'Grocer,' March 3; 'Journal of the Society of Arts,' March 3; 'Grocery News,' March 3; 'Produce Markets Review,' March 3; Practical Magazine,' for March; 'Educational Times,' for March; 'British Journal of Dental Science,' for March; 'Journal of Applied Science,' for March; 'American Journal of Pharmacy,' for March; 'Pharmacist,' for March; 'Canadian Pharmaceutical Journal,' for March; 'Moniteur Scientifique,' for March; 'Pharmaceutische Zeitung,' for March 3; Sanitary Record,' for March 3; 'Medical Examiner,' for March 3.

Notes and Queries.

[541]. CASE HARDENING COMPOSITION.—Can any of your readers give me a recipe for a good Case Hardening Composition?

IRON.

BOOKS, PAMPHLETS, ETC., RECEIVED.

A PRIMER OF CHEMISTRY, INCLUDING ANALYSIS. By ARTHUR VACHER. London: J. and A. Churchill. 1877. From the Publishers.

Obituary.

Notice has been received of the death of the following:—

On the 5th of February, 1877, Mr. Thomas Wilkinson, Chemist and Druggist, Bishop Auckland. Aged 29 years.

On the 10th of February, 1877, Mr. Charles Holloway, Chemist and Druggist, Birmingham. Aged 71 years.

On the 16th of February, 1877, Mr. Joseph Gibbons Lewis, Chemist and Druggist, Brunswick Road, Liverpool. Aged 43 years.

On the 20th of February, 1877, Mr. James Martin Wellington, Pharmaceutical Chemist, Oakham, Rutland. Aged 70 years. Mr. Wellington had been a Member of the Pharmaceutical Society since 1842.

On the 21st of February, 1877, Mr. Marcus Fitzwilliam Mitchell, Chemist and Druggist, London Street, W. Aged 32 years. Mr. Mitchell had been an Associate of the Pharmaceutical Society since 1869.

On the 26th of February, 1877, Mr. William Thomas Holden, Chemist and Druggist, Hull. Aged 63 years.

On the 26th of February, after a few days' severe illness, Mr. John William Steel, Chemist and Druggist, Beccles, Suffolk. Aged 34 years.

On the 4th of March, 1877, Mr. Josiah Matthew, Chemist and Druggist, Dalston. Aged 56 years. Mr. Matthew had been an Associate of the Society since 1870.

On the 4th March, 1877, Mr. Walter Breton, Pharmaceutical Chemist, Greenwich. Aged 45 years. Mr. Breton had been a Member of the Pharmaceutical Society since 1858.

THE PHARMACEUTICAL SOCIETY OF IRELAND.

A Copy of the following letter addressed by Dr. J. Emerson Reynolds, Professor of Chemistry, University of Dublin, to the President of the Pharmaceutical Society of Ireland, has been sent to us, and as it may afford some idea of the progress being made in working the Pharmacy Act in Ireland, we place it before our readers.

"*Dublin, Feb.* 14, 1877.

"My dear Sir Dominic,

"I regret the Council of the Pharmaceutical Society of Ireland have, by their adverse vote of the 7th inst. upon my resolution, declined to adopt the plan of testing each candidate's knowledge of practical chemistry by a sufficiently long examination in a suitable chemical laboratory.

"I first brought this subject before the Council when the examination programme was under discussion last year, and before examiners were appointed; but, yielding to the wishes of some of the members, I did not press the matter beyond a general resolution.

"In the interval the examinations in chemistry, as far as they could go, have been ably conducted by your present examiner with the limited means at his disposal.

"At the termination of the "year of grace," however, I again urged the Council to require all candidates for the Society's certificate to work out suitable exercises in synthetical and analytical chemistry during at least two hours. As it is expedient that a number of candidates should be examined at the same time without risk of communicating, the practical testing I contemplated could only be conducted in a large and suitably fitted laboratory, hence I offered to give the Council material aid in obtaining the necessary accommodation. As no action was taken then I brought the subject forward for the third time and after full notice, on the 7th instant, when my resolution was rejected by a majority of two.

"I cannot agree with those who think that there would be any danger to the Society or hardship to candidates for the certificate of "Pharmaceutical Chemist" in asking them to undergo a two hours' laboratory examination, when more is demanded in England, and when we require candidates for medical degrees and for special arts' courses in the University of Dublin to be examined for at least *three hours* in the College laboratory.

"Under the circumstances, however, I cannot continue to be a consenting party to the issue of the certificates above referred to, and therefore beg to resign my seat at the Council.

"I am, my dear Sir Dominic,
"Very faithfully yours,
"J. EMERSON REYNOLDS.

"To Sir Dominic J. Cardigan, Bart.,
"President,
"Pharmaceutical Society of Ireland."

THE BOTANICAL PRIZE.

Sir,—I was very pleased on reading Mr. Hanbury's good suggestions concerning the regulations under which the Pharmaceutical Herbarium is formed.

I will not say anything respecting paragraphs Nos. 1, 2, 3, 4, 5 and 6 of the article of April 29, of which Mr. Hanbury speaks; I will leave those for far more able pens than my own to criticize, but, still I think I must say a few words respecting Nos. 7, that is,—"Candidates must not exceed the age of 21 years."

I have no doubt it places a great many assistants in the same predicament as it does myself, viz., being just over 20 years of age, I cannot compete for the Herbarium Medal on that account. I should have had a try for the forthcoming one in June, but owing to an illness which confined me to the house for two months, I was unable to do so.

I am quite of the opinion of Mr. Hanbury, that as students cannot go up for the Minor or Major until they have attained the age of 21 years, the age of young men ought not to be restricted to such a limit, for I have no doubt, were the standard of age raised to 24, or even 25, the Herbaria sent up would be more than twice as many and far better in respect to number, preserving and classification of specimens.

I trust those in power may fully consider the matter.

J. HEIGHINGTON.

Bridport, March 5, 1877.

MILK OF SULPHUR.

Sir,—After the appearance of Professor Redwood's letter I did not intend to intrude myself again on your columns respecting the much vexed Milk of Sulphur question. I was quite content, despite the Professor's being so elaborate an article, to let your readers "look on this picture and on that," without any addition being made to my humble effort, but were I to allow to pass unnoticed Mr. Slipper's remarks on my "*ipse dixit*," he and others might conclude that it was only an "*ipse dixit*," and worth no more than his own.

Dr. Bell, in his examination at Runcorn, stated that out of nine samples of "milk of sulphur" purchased for analysis in Salford (North of England) only one was contaminated. In Southampton (South of England) there are twenty-five druggists' shops: the borough analyst a short time since procured a sample of "milk of sulphur" from each, of which only three were found contaminated. These statistics do not prove "a great and continuous demand" for the contaminated article, they certainly prove the contrary, *ergo* Mr. Slipper's *ipse dixit* is only an *ipse dixit*, while the truth of mine is corroborated by facts. Twenty-five years ago these figures without doubt would have been reversed, and there can be little doubt in any unprejudiced mind that the demand for the contaminated article must be growing, and will grow, less and less.

The adulteration of Foods and Drugs Acts were specially passed to protect the poor. They were not passed because it was known or suspected that such adulterated articles were sold at high prices to the rich and educated in such places as Bond Street and Plough Court, but because it was known or suspected that they were sold at low prices to the poor and uneducated in such places as Seven Dials and Petticoat Lane, and kindred metropolitan and provincial localities.

What Mr. Mee said so tersely in a dozen lines in your issue of the 3rd of February is possibly the most to the point of all that has been written on the subject. There is little doubt that the lawyers will soon cut the Milk of Sulphur gordian knot in the way he intimates. It were hard indeed on the grocers to compel them to declare when they sell a sophisticated coffee, if the druggists may sell sophisticated milk of sulphur without a similar declaration. Mr. Slipper will not lose his patrons by being unable to sell them the whiter article of which they are so enamoured, but while supplying them, he will be compelled to assist in educating them, by teaching them that the article he sells them is contaminated with sulphate of lime.

In past Pharmacopœias "Lac Sulphuris" has been ordered to be prepared by alternative processes, one of which would yield an impure and the other a pure article. At different times in past Pharmacopœias, but more recent ones than those to which I have just alluded, "Sulphur Præcipitatum" has been ordered to be prepared by processes one of which would produce the impure and the other and later the pure article. Therefore how more than idle it is to contend that "Milk of Sulphur" is the equivalent of sulphur *cum* lime, and "Precipitated Sulphur" of pure sulphur.

Mr. Slipper is painfully illogical; he would always for "milk of sulphur" sell the contaminated article to his customers, he would never dispense for "lac sulphuris" other than the pure if written in a physician's prescription. Why he would make fish of one and fowl of the other it were hard to tell. He certainly should make at least one exception to the rule he lays down for his guidance—viz., when prescribed for himself.

Mr. Slipper praises "the common sense and skill" which Professor Redwood has by tongue and pen displayed in the matter, but the Professor is logical, and consequently would do the very reverse of what Mr. Slipper says he would do with such prescriptions.

ROBERT CHIPPERFIELD.

Southampton, Feb. 22, 1877.

THE ADMINISTRATION OF PHOSPHORUS.

Sir,—The last two numbers of the *Pharmaceutical Journal* (pp. 694 and 712) have contained an interesting account of the preparation and administration of phosphorated cod liver oil, by Dr. E. R. Squibb, of Brooklyn. He gives a process for making a one per cent. solution of phosphorus in cod liver oil by employing heat and shaking the two together in an atmosphere of carbonic acid. By this means he avoids the liability to oxidation of the phosphorus and the formation of the pellicle on the surface of the oil, and subsequent dark brown deposit on the sides and bottom of the bottle, which have always given so much trouble to those who have attempted to make it. So much does this latter difficulty stand in the way that, according to the formula* of one who makes it largely, he directs a solution of phosphorus in almond oil to be made first and this diluted with sufficient cod liver oil to make it the required strength. This process, I believe first suggested by M. Méhu,† is now generally adopted, taking so much phosphorated oil of the British Pharmacopœia and adding the requisite quantity of cod liver oil. The subject has been well and carefully investigated by M. Méhu,‡ who holds that the most stable solution of phosphorus in oil is in almond oil that has been carefully superheated (I am glad here to be able to corroborate M. Méhu, now that I find, as he says, it stands exposure to light better).

Dr. Squibb prefers the cod liver oil solution because on the authority of Mr. J. Ashburton Thompson, and others

* *Pharm. Journ.*, Nov. 11, 1876, p. 407.
† *Pharm. Journ.*, July 2, 1875, p. 3.
‡ *Pharm. Journ.*, July 2, 1875, p. 3.

cited by Mr. Thompson, he states that it "seems to have been pretty clearly shown" "that its solution in vegetable oils is liable to develop poisonous properties, which render these variable and unsafe; and it is supposed that this is due to the formation of hypophosphorous acid, by a reaction between the phosphorus and certain elements of the oils, under the influence of light, air and moisture." Too much credence, according to many authorities with whom I have communicated, seems to have been placed by Dr. Squibb on Mr. Thompson's statements. Most of the solutions of phosphorus in vegetable oils are poisonous, because they are active, definite, and stable in comparison with the ethereal, alcoholic, and cod-liver oil solutions which Mr. Thompson recommends. As was pointed out by your reviewer of his work,* the quantity of phosphorus given in ethereal solution could not have been one-fourth that mentioned by him, *i. e.*, one-fifth to three tenths of a grain three times a day, to a boy of ten years. Because four grammes of phosphorus are ordered to be macerated in 200 grammes of pure ether it is taken for granted that it will be all dissolved. Whereas if saturated it cannot hold in solution more than one-third of that quantity at the ordinary temperature. Reckoning on such assumption one cannot wonder that stable phosphorated vegetable oils given in doses containing an amount of phosphorus equivalent to that which Mr. Thompson supposed he was giving in phosphorated ether produced poisonous effects. It has also been shown that the supposition of their poisonous action being due to the formation of hypophosphorous acid in the phosphorated vegetable oils was erroneous. A sample of phosphorated almond oil containing one per cent. of phosphorus, which I kept for years, gave but a very faintly acid reaction to litmus paper; and hypophosphorous acid and the hypophosphites are both frequently used in medicine in doses above those which could be contained in medicinal doses of phosphorated oil.

In my hands (I have not tried Dr. Squibb's process) I have found phosphorated cod-liver oil very prone to change. On keeping there is always a dark-brown deposit quickly formed on the bottom and sides of the bottle. This must detract from its strength, and probably account for the palatability (?) of phosphorated cod liver oil in comparison with an equivalent dose administered in other forms. I do not think that it will be conceded here that "its solution in cod liver oil is the best" form of administering phosphorus. I should be glad if Dr. Squibb or Mr. Thompson would set the matter at rest in regard to the poisonous property of phosphorated vegetable oils in comparison with that of phosphorated animal oils, by physiological experiments on dogs or other animals with samples, of each oil carefully prepared and of equal strength.

Dr. Squibb's suggestive mode of administering phosphorated cod liver oil with glyconin and in powder is worthy of attention in regard to its appliance to phosphorated almond oil.

AN ADULTERATION OF ACONITE ROOT.

BY E. M. HOLMES, F.L.S.,

Curator of the Museum of the Pharmaceutical Society.

Aconite root possesses such powerful properties that it is very important the medicinal article should be, as far as possible, of uniform strength and quality. Yet this is by no means the case, for it is difficult to find in a commercial sample one root in a dozen which upon fracture appears sound and in good condition. This is due, according to Hanbury, to its being gathered indiscriminately by peasants, who regard neither the most advantageous time for collection, nor the proper species. This is not to be wondered at considering that the wholesale price in this country is as low as 6*d.* per lb. As the root is sold by the German peasants to buyers who obtain a profit by supplying wholesale dealers in Germany, and these again have to obtain a profit before it is exported to this country, it is obvious that the prices paid to the peasants must be too small to pay for careful collection.

In some districts aconite root is said to be gathered by intelligent herb and root collectors who are well acquainted with the plants they gather, but what is collected by them is probably retained for home consumption, and the inferior samples exported.

From the cheapness of the root, and from the fact that few roots have the distinctly conical appearance of aconite, it is evident that it would scarcely pay to adulterate it. Adulteration then must either result from careless collection, or from accidental admixture.

The root which has lately been found mixed with aconite is that of Masterwort, *Imperatoria Ostruthium*, L., an umbelliferous plant, official in the Edinburgh Pharmacopœia so late as 1792. It is a native of mountainous countries and grows in similar districts to those in which aconite is found. As it is still official in the German Pharmacopœia, its accidental occurrence in aconite root from Germany is not surprising.

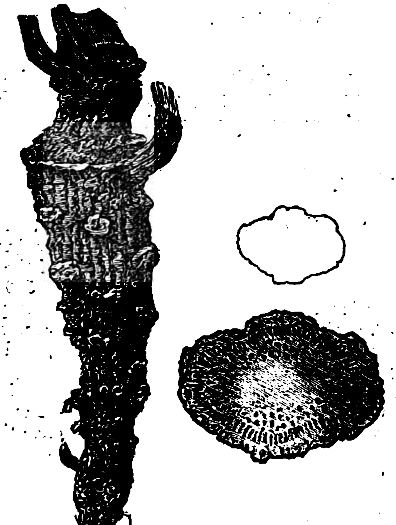

Fig. 1.—*Imperatoria Ostruthium.**

Its value in this country is double that of aconite root, and it is obvious therefore that it has not been purposely used as an adulteration.

In the sample examined, the masterwort root amounted to about 5 per cent.

The characters by which it may be distinguished from aconite root are as follows :—

The rootstock, fig. 1, for it is properly so called, is less tapering than aconite root, is slightly compressed, and exhibits several warty zones indicating periods of growth. In some specimens, these are much less prominent than in others, but can always be traced. The whole of the rootstock is finely wrinkled transversely, so as to give it a somewhat annulated appearance. The transverse section presents very marked characters. The central portion is of a yellowish white colour, and exhibits a more or less complete ring of brownish dots. The portion next the bark presents elongated dots of a paler colour, which give this portion of the section a radiate appearance. With the aid of a lens, these dots are seen to be filled with an oily or resinous substance. The cortical portion is very thin. The rootstock has an odour comparable to bruised ivy leaves, or to the plant commonly known as cow parsley (*Chærophyllum sylvestre*, L.), and a pungent slightly bitter taste.

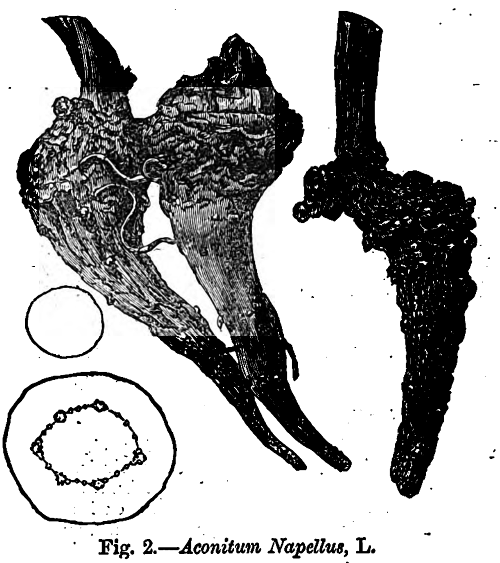

Fig. 2.—*Aconitum Napellus*, L.

Aconite root is very variable in appearance internally; frequently the centre is quite hollow. Some pieces have a brownish colour, others are white and starchy, and a few present a resinous fracture. In a sound root, however, which is usually starchy or slightly resinous, a faint line may generally be traced, which marks out the meditullium. This line has usually five to nine prominent angles, see fig. 2, the number of angles being larger as the section approaches the top of the root. If the root be wetted and examined with a lens, the line is seen to consist of an irregular line of vessels, which form small bundles in the apex of the projecting angles. The cortical portion occupies nearly half of the circumference of the root.

From the above characters it will be observed that the

* In the woodcuts the roots are represented of the natural size; the sections are shown both of the natural size and magnified.

presence of oil receptacles in the masterwort root at once distinguishes it from aconite. A spiritous tincture of masterwort when dropped into water gives a blue fluorescence resembling that of quinine, and a slight milkiness, and communicates to the water its peculiar odour. By these characters its presence might probably be detected in a mixture containing tincture of aconite.

Although the small percentage in the sample examined would lead to but very slight diminution of strength in the tincture of aconite made from it, yet the appearance and odour communicated to a mixture containing such a tincture might lead to much inconvenience in pharmacy, and throw discredit upon the dispensing department.

It is quite time that the attention of cultivators of medicinal plants in this country should be drawn to the bad quality of the imported root, and that attempts should be made to cultivate it extensively in this country. It is very probable that, as in the case of henbane, a good article would command a fairly remunerative price. It is obvious, also, that until it is possible to obtain a plentiful supply of the roots of *Aconitum Napellus*, free from any admixture of other species, it will not be possible to obtain an accurate knowledge of the alkaloids contained in that species.

SILPHION OF THE ANCIENTS AND ITS ALLEGED MODERN REPRESENTATIVE.

BY M. HERINCQ.

About three years since* allusion was made in this Journal to a report that a plant found in the Cyrenaica, and called by the natives "*drias*" (*Thapsium Silphium*) possessed surprising curative properties, and was claimed to be identical with the ancient silphion, the plant from which the precious "laserpitium" was extracted. Since that time this claim has been put forward more prominently, and under the name of *Silphium Cyrenaicum* the plant has been introduced as a specialty by a French homœopathic house. This claim has been disputed rather warmly, and the subject being brought before the Société Botanique de France in 1874, and the materials for an examination being deficient, a wish was expressed that some botanist should examine this plant in the alleged place of its growth. This was done in 1875 by M. Daveau, principal of the seed department of the Natural History Museum in Paris, who brought home from the Cyrenaica a complete set of specimens of the so-called *Silphium Cyrenaicum*. The conclusion he came to was that the plant was identical with *Thapsia garganica*. The subject, however, still appears to excite interest, and in a pamphlet issued by M. F. Herincq, an attaché at the Museum of Natural History, Paris, the whole subject is treated in a very thorough manner.† The conclusion arrived at will be best shown by the following extracts which, by the courtesy of M. Herincq in placing *clichés* at our disposal, we are enabled to illustrate. In order to avoid confusion, the author uses the word "Silphion" when speaking of the plant of the ancients, and "Silphium" when referring to that of the moderns.

The Greeks gave the name "Silphion" (Σιλφιον) and the Romans "Laserpitium" to a plant which grew more particularly in the Cyrenaica and which yielded a gum resin when incisions were made in the root or stem. This gum resin was called "Laseros" by the Greeks, and "Laser" by the Romans, and was emplowed as a condiment. Marvellous properties were also attributed to it, such as giving sight, healing poisoned wounds, and restoring youth. It was sold for its weight in gold. The plant was said to have had a supernatural origin. According to Greek authors, seven years before the foundation of Cyrene, silphion was suddenly produced by a kind of pulverulent rain that fell in Africa, in the neighbourhood of the garden of the Hesperides and the Syrtis Major; the productive energy of this rain extended over 4000 stadia.

All authors agree in saying that the silphion gradually became more rare in the Cyrenaica from the first century in the Christian era, and that at last it disappeared completely; but they explain this disappearance in various ways. Pliny says that in his time only a single specimen of this plant was to be found in the Cyrenaica, and that it was sent to the Emperor Nero. However this may be the silphion became unknown to succeeding generations, and its representation is now only found upon medals or coins bearing on one side figures of various parts of the plant (stem, root, and seeds) and on the other the head of Jupiter Ammon.

Numerous researches have been made with the object of ascertaining to what, if any, existing plant the ancient silphion should be referred. It has been generally accepted, thought without proof, that the *laser* was produced by an umbellifer; but with respect to the species or even the genus there has been no such unanimity. Several plants growing in Africa have been successively indicated: *Thapsia garganica, Ferula tingitana, Laserpitium gummiferum, Ferula asafœtida, Laserpitium Siler*, etc. In 1817, Della Cella brought from the Cyrenaica several plants, among which was an umbellifer that he supposed to be the silphion of the ancients. Viviani thought he recognized in it the characters of the silphion of the coins, and also a great resemblance to the *Thapsia garganica*, and named it *Thapsia Silphium*. But the theory was not accepted as proved, for in 1826, when the Société de Géographie instituted a prize for the description of the Cyrenaica, it expressed a wish that a search should be made for the silphion among the plants of the country. M. Pacho, who obtained the prize, collected the *Thapsia Silphium* of Della Cella and Viviani, and believed it was the silphion of the ancients; but hesitated to pronounce definitely, because he had found his plants upon the northern hills of the district, whilst the geographical indications for the plant marked its place further south.

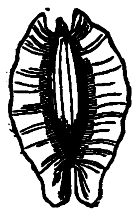
The question was in this state when, in 1873, Dr. Laval, médecin-major in the military hospital at Valenciennes, sent to the Jardin d'Acclimatation, Paris, some seeds, labelled "Seeds of Cyrenaican Silphion," and accompanied by the following note: "This plant grows abundantly around the ruins of Cyrene and other cities of the Libyan pentapolis, upon plateaux elevated 200 to 500 metres above the level of the sea, and exposed to a temperature of 15° C. during the months of December, January, and February. It seems to prefer sandy soils, and flowers during April and May."

The seeds were sent to the Muséum d'Histoire Naturelle to receive their botanical name, and the author was the first to examine them. He saw at once that they belonged to a *Thapsia*, and by comparing them with seeds of various species of the genus he was convinced that they belonged to the *Thapsia garganica*, Linn., a plant growing in Algeria, Spain, Italy and all the regions on both coasts of the Mediterranean. This opinion was confirmed by other competent authorities, but did not satisfy Dr. Laval, who visited the Museum to point out the differences he considered to exist between the *Thapsia garganica* and his *Thapsia Silphium*, which he asserted was identical with the famous silphion of the Greeks. It was then that the author first heard of the wonderful cures which it was alleged had been worked with an extract prepared from the plant. There appears to have been little difficulty, however, in demonstrating that these seeds presented no character distinguishing them

* *Pharm. Journ.* [3], vol. iv., p. 598.

† La Vérité sur le Prétendu Silphion de la Cyrenaique: ce qu'il est; ce qu'il n'est pas. Par M. Herincq. Second edition. 51 pp. and map. Paris: Lauwereyns.

from those of *Thapsia garganica*, as will be seen from the following sketches:—



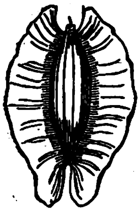


Fig. 1. *Silphium Cyrenaicum*. Fig. 2. *Thapsia garganica.*

The dispute then turned upon the leaves, Dr. Laval claiming that the segments were terminated by three lobes and that this was not the case with the leaves of the *Thapsia garganica*; but this was easily settled by the herbarium specimens. When Viviani published his 'Floræ Libycæ' he had to assist him in his diagnosis of *T. garganica* only the description by Linnæus, in which the trifid character of the terminal segments is not very clearly indicated. Viviani was thus misled when describing Della Cella's plant, which is also Laval's *Silphium Cyrenaicum*, into making it a new species as *Thapsia Silphium*, close to *T. garganica*, with the remark, "cui nostra species valde proxima." A comparison, however, of the later description of *T. garganica* by De Candolle with that by Viviani of *T. Silphium* will leave no doubt, the author thinks, in the mind of a botanist that they refer to the same plant. They are as follows:—

"*Thapsia garganica* (DC. Prod. iv. 202).—Foliis bi-tri-pinnatisectis, nitidis, laciniis linearibus acutis elongatis, secus margines integerrimis. Variat petiolis glabris aut pilis sparsis subhirsutis."

"*Thapsia Silphium* (Viviani, Flor. Libycæ, 117).—Foliis pinnatis, foliolis multipartitis, laciniis simplicibus trifidis, omnibus linearibus elongatis, utrinque hirsutis, margine revolutis."

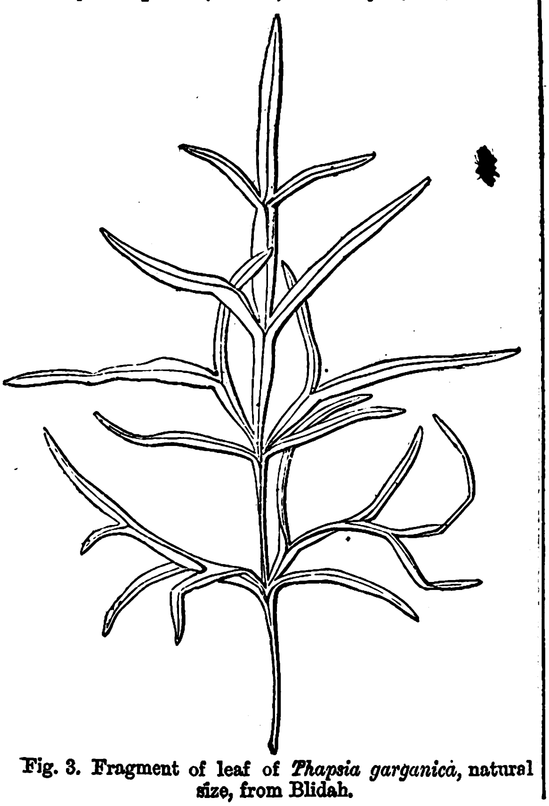

Fig. 3. Fragment of leaf of *Thapsia garganica*, natural size, from Blidah.

The "margine revolutis" of Viviani the author explains as the result of a badly prepared specimen, he having met with a similar appearance in other herbarium specimens of *T. garganica*. The illustrations (figs. 3 and 4) represent a fragment of a leaf of *Thapsia garganica*, collected in the Blidah, and one of *Silphium Cyrenaicum (T. Silphium)* collected under the superintendence of Dr. Laval himself.

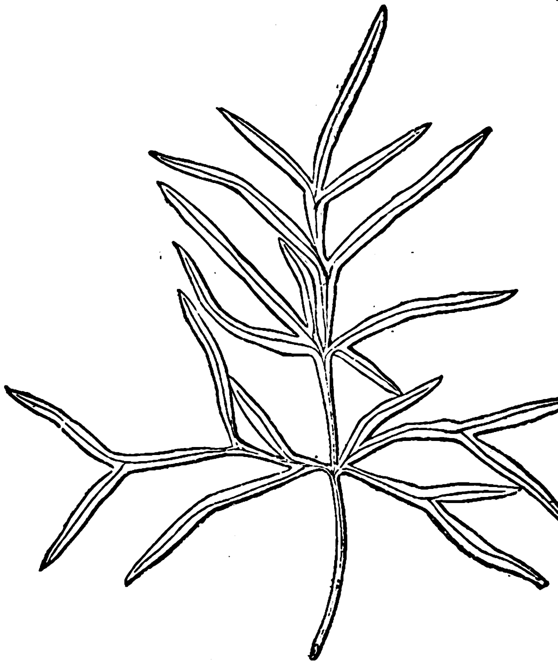

Fig. 4. Fragment of leaf of *Silphium Cyrenaicum*, natural size, from the Cyrenaica.

Further, M. Daveau, who met with Dr. Laval's plant between Benghazi and Dernah in 1875, says, "The leaves are divided exactly like those of *Thapsia garganica*, and I have also observed more or less villosity. The radical leaves are much more developed than those inserted on the stems, which are alternate with one another."

The dispute next raged about the roots, the advocates of silphium contending that the *Thapsia garganica* has a tap-root, *sometimes* bifurcated at its extremity, whilst the *T. Silphium* has numerous large *creeping* divergent horizontal roots, the principal stock giving rise to four to eight rhizomes which attain a length 0·70 to 0·80 metres, and where their extremity reaches the surface give rise to a new stock. To this the author replies that the root of *Thapsia garganica* is *always* bifurcated when of a certain age, and that he has received from Algeria specimens having three, four, and even nine bifurcations, all very horizontal. As to the four to eight rhizomes springing from the principal stock, which is put forward as characteristic of *Silphium Cyrenaicum*, the author remarks that this character belongs to all the perennial umbellifers, except the length, and that no botanist would admit these creeping roots, 80 centimetres long, giving rise to new stocks where their extremities touch the surface of the soil. Concerning this point, M. Daveau says, "The root of this plant, which at all ages is brown, is simple while young, becoming branched when older, like that of *Thapsia garganica* if it grows in arid and stony soil, conditions that are met with in the Cyrenaican soil. The divisions of the roots sometimes shoot perpendicularly into the soil, sometimes more horizontally, but in no case do they give rise to adventitious buds upon approaching the surface of the soil. This mode of multiplication,

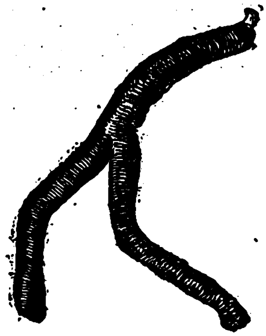

Fig. 5. Bifurcated root of *Silphium Cyrenaicum.*

Fig. 6. Bifurcated root of *Thapsia garganica.*

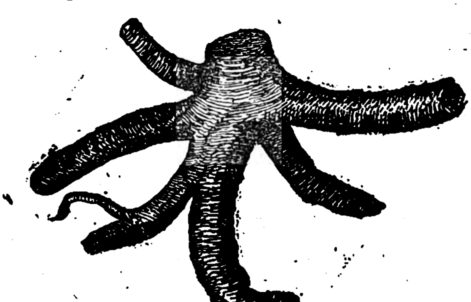

Fig. 7. Old stock, with multiplied roots, of *Silphium Cyrenaicum.*

Fig. 8. Old stock, with multiplied roots, of *Thapsia garganica.*

which is said to be the only one with this plant, is materially impossible, as the stalks of the *Thapsia Silphium* are separated in most cases by a distance of twenty metres. Moreover they frequently extend into the crevices of the rocks, where it would be impossible for them to form runners. Figs. 5, 6, 7, 8, represent the roots.

Having finished his argument that the *Thapsium Silphium* of Viviani (*Silphium Cyrenaicum* of Dr. Laval) is identical with *Thapsia garganica* of Algeria, Spain and Italy, the author proceeds to demonstrate that it cannot be the Silphion of the Greeks.

Professor Oersted, in his memoir on the subject,* arrived at the conclusion from a study of the designs on ancient coins that the silphion was probably a species of *Narthex,* which in anticipation of its discovery at some time he proposed to name *Narthex Silphion.* On the other hand Dr. Laval claims that the figures on the coins agree with the characters of his plant. M. Herincq, however, remembering the difficulties experienced every day in naming certain species when surrounded by all the

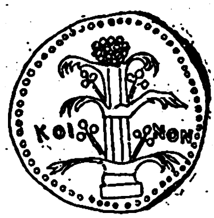

Fig. 9. Coin showing the Silphion Plant.

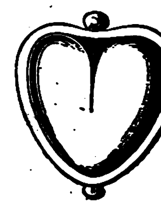

Fig. 10. Coin showing the Silphion Fruit.

facilities of a modern herbarium, does not admit the possibility of deciding satisfactorily from the designs on coins. But so far as he admits such evidence he claims that the opposite connate leaves and the heart-shaped seeds (see figs. 9 and 10) are not indicative of an umbelliferous plant at all. The arguments that M. Herincq prefers

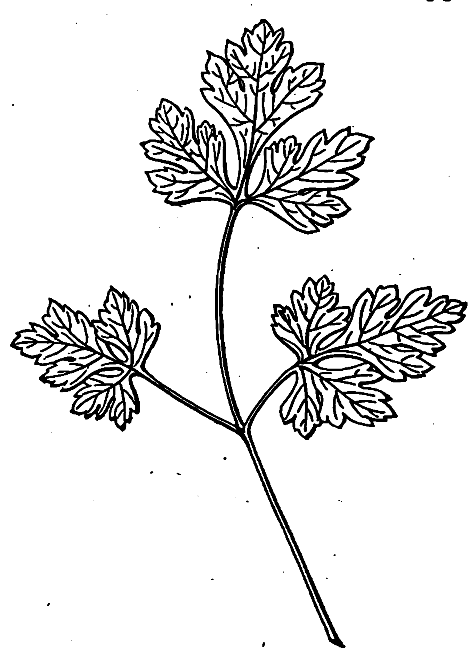

Fig. 11. Fragment parsley leaf.

* See *Pharm. Journ.* [3], vol. iii., p. 1012.

to rely on as proving that the *Silphium Cyrenaicum* of Dr. Laval is not the silphion of the ancients are briefly as follow:—

(1.) Theophrastus says (lib. vii., c. 8), "The stem of the silphion is as large as the ferula; its leaf resembles that of parsley."

According to Dioscorides (lib. iii., c. 78), "The seed was large and the leaves were similar to those of parsley." According to Pliny, "the seed was folded like a leaf; the bark of the root was black; the leaves resembled strongly those of parsley, and burst in the spring." The force of these quotations will be best seen by comparing the drawing of a fragment of parsley leaf (fig. 11) with that of a fragment of a leaf of *Silphium Cyrenaicum* (fig. 4).

(2.) The taste of the juice of the ancient silphion is represented by the Latin *acer*, and Greek ἀκη, pungent, sharp, tart; but nothing is said of its irritating properties, or of a vesicating principle, or of any process being necessary to render it inoffensive. On the contrary the juice of the *Silphium Cyrenaicum* is composed of two principles, one vesicant, the other resolvent, and it is indispensable that the vesicant portion be removed before the juice is administered internally.

(3.) All ancient authors agree in saying that animals were nourished by the use of silphion, and that their flesh was improved. But the *Silphium Cyrenaicum* is considered poisonous to animals. Dr. Reboux, writing to the Botanical Society of France in 1875, says, "The straw drawn from the region where it abounds is not given to asses or mules until it has been carefully examined and ascertained to be free from fragments of stalks and seeds of *Silphium Cyrenaicum*. Cauvet, in his 'Elements of Medical Natural History,' says, "It is known that the drivers carefully muzzle their camels and asses whilst passing through the district where this plant grows. It is alleged that a single seed is sufficient to provoke in an animal an intense diarrhœa and even to cause death."

(4.) The silphion of the Greeks, or laserpitium of the Romans, was considered a universal medicine, but it was also, and especially, a very choice condiment for gourmands. Pliny says, "After truffles and mushrooms laserpitium takes the first rank." Dioscorides says that the root was eaten mixed with salt, to give a more agreeable flavour to the meats. Lastly, Theophrastus says that the roots brought to Athens were preserved and put into pots with flour, but that they were equally good, eaten fresh, cut into slices and seasoned with vinegar. Now the plant collected by Laval could not be reckoned a condiment, and nobody would venture to eat the fresh root cut into slices. But even when deprived of its vesicating principle it appears not to be entirely without danger, it being stated that half the number of granules containing the aqueous extract that can be taken without inconvenience in one case will induce spitting of blood and symptoms of suffocation in others.

As to the therapeutic side of the question, M. Herincq contents himself with giving a long list of the ailments for which the ancient silphion was held in repute, and denying that there is evidence that in this respect either that the *Silphium Cyrenaicum* of Dr. Laval, or, as M. Herincq will have it, the *Thapsia garganica*, Linn., is the representative of the silphion of olden times.

NOTES ON PERFUMERY.*

BY W. SAUNDERS, LONDON, ONTARIO.

The art of compounding perfumes is an ancient one. It was practised by the early Egyptians and other Oriental nations, and with them perfumes were in frequent use. In Holy Writ, Moses speaks of being directed to take sweet spices, stacte, onycha, galbanum and frankincense, and confection them into a pure and holy perfume after the manner of the apothecary, to be offered up to the Lord; and in Proverbs we read of epicures indulging in the luxurious use of costly perfumes. The Greeks and Romans used perfumes freely, as well on their persons as at their feasts; they were also used with flowers at sacrifices to regale the gods. These fragrant compounds were in demand for theatres and other places where crowded audiences assembled, when their use subdued the offensiveness of a vitiated atmosphere.

From the frequent mention of perfumes in the form of ointment, it would appear that the solvent powers of fatty matters over the odorous principles of flowers were among the earlier discoveries in this department. Subsequently fragrant waters were in great demand, and, costly as these articles of luxury then were, they were nevertheless largely consumed. Grave men at times protested against the prevailing extravagance, and philosophers declared their aversion to perfumes. "There is the same smell," said Socrates, "in a gentleman and a slave when both are perfumed;" hence, in his opinion, the only odours desirable were those arising from honourable toils and "the smell of gentility;" but in spite protests the wealthy perversely and persistently followed their own tastes, anointed their bodies, pomaded their hair and bathed their limbs in fragrant waters, as though the thoughtful ones had never spoken.

In later times, with the advance of civilization, the use of perfumes gradually extended to other nations, culminating in their general use throughout the civilized world. In some countries there was for a time stout opposition to the introduction of all such preparations. In England it was seriously thought to be a fit subject for legislative control. In 1770 (?) an Act was introduced into the English Parliament as follows: "That all women, of whatever age, rank, profession or degree, whether virgins, maids, or widows, that shall from and after such Act, impose upon, seduce and betray into matrimony any of his majesty's subjects by the scents, paints, cosmetic washes, artificial teeth, false hair, iron stays, hoops, high-heeled shoes, bolstered hips, shall incur the penalty of the law now in force against witchcraft and like misdemeanours, and that the marriage, upon conviction, shall stand null and void."

In large cities the manufacture and sale of perfumery is sometimes carried on as a separate occupation, yet as a rule this department of business as in ancient days is still associated with the trade and mysteries of the apothecary. Some may perhaps have but little sympathy with the manufacturer of perfumery, and may think that it were better handed over to the hairdresser or dealer in notions, and that the apothecary should devote his time exclusively to the more important duties of dealing out medicines, pure and simple, to meet the requirements of physicians and the wants of suffering humanity. This latter is doubtless the most legitimate and beneficent exercise of the apothecaries' skill, and ought always to be regarded as of primary importance, yet he will often have spare hours when he can enjoy the pleasures connected with the compounding and blending of odours, and at the same time develop a profitable and time-honoured branch of his business

The cultivation of the olfactories is an advantage to the pharmacist. The nose is an organ whose importance he cannot ignore in his business, and it is doubtful if better training can be found for it than in the compounding of perfumes. We all think it a gain to have a fine ear for music; why should we think less of an exquisite nose for odours? Surely this prominent member is as capable of cultivation as is the ear, not that an unusual development is desirable in either case, but rather the making the very best use of the organs with which we have been supplied. There are harmonies and discords in perfumes as in music; Piesse has reduced these to a scale which he calls the gamut of odours. "If," says he, "a perfumer desires to make a bouquet from primitive odours, he must take such odours as chord together; the perfume will then be harmonious."

* Read before the American Pharmaceutical Association.

For some time past the tendency has been to turn over the manufacture of perfumes too much to the specialist. This has probably resulted mainly from two causes,—first, the difficulty of procuring the materials used in the making of perfumes in a state of purity, and in the second place for want of plain and practical information on the subject. The first obstacle is less felt now than formerly, and to aid in the removal of the second is the main object of the present paper. My purpose is to place within the reach of every one of our members such information as will enable him, with a little attention, to equal the finest productions of a Lubin, an Atkinson, or a Rimmell. I shall first briefly refer to the ingredients which enter into their composition, and afterwards give the formula for their production.

Alcohol.—One of the first requisites in the manufacture of good perfumes is pure alcohol, free from fusel oil or other foreign flavour. This purer grade of spirit is known in commerce as pure spirits, silent spirits, or deodorized alcohol, and may readily be distinguished from ordinary alcohol by the absence of that peculiar pungency of odour which is present to a greater or less extent in most commercial samples.

Ottos or Essential Oils.—It is of the greatest importance that these should be strictly pure and of the finest quality.

Pomades.—From these are prepared some of the simple extracts in the appended formulas, such as jasmine, tuberose and cassia. The quality must be that known as triple pomade. The simple extracts are prepared as follows: one pound of the pomade is cut in small pieces and placed in a bottle of sufficient capacity, in which is put a pint of pure spirit. Place the bottle suitably stoppered in a water-bath, and apply heat sufficient to barely melt the pomade, shake well together, and repeat the shaking frequently until the fatty matter solidifies. In this way the pomade will be reduced to a finely divided or granular state, permeated thoroughly by the spirit. Allow this to stand for several days, giving it an occasional shake, then drain off the liquid extract into another bottle; if this fall short of a pint repeat the operation with a sufficient quantity of alcohol to make up to this measure. By subsequent and similar treatment, a second and even a third quantity of extract may be made, which, although much weaker, will be found useful in the preparation of cheaper perfumes.

Extract of Orris.—Seven pounds of finely ground orris root of good quality is treated by percolation with pure alcohol until one gallon of extract is obtained.

Extract Vanilla.—Four ounces of vanilla beans of the finest quality powdered finely in a mortar with a sufficient quantity of dry white sugar (from four to six ounces), pack in a percolator, and percolate with proof spirit until one gallon is obtained.

Extract Tonka.—Take one pound of tonka beans, reduce to a coarse powder, and percolate with alcohol, to make one gallon.

Extract Musk.—Take of pure grain musk of the first quality two drachms. Mix half an ounce of liquor potassæ with four ounces of proof spirit, and triturate the musk with this mixture until it is thoroughly softened, and reduced to a creamy state; add enough proof spirit to make up about one pint; stir well, then allow the coarser particles to subside, and pour of the supernatant fluid. Rub the coarser portions again with a fresh portion of spirit, proceeding as before, and repeat the process until the musk is entirely reduced, and the quantity of extract measures three pints. Allow this to stand for a fortnight with occasional shaking, when it will be ready for use.

Extract Styrax.—Eight drachms of styrax balsam dissolved in one pint of alcohol.

Benzoic Acid.—Only that prepared from gum benzoin should be used.

FORMULAS.

Jockey Club.

Ext. Jasmin	5 ounces.
„ Orris	20 „
„ Musk	7 „
„ Vanilla	1½ „
Otto Rose, Virgin	1½ drachms
„ Santal. Flav	1½ „
„ Bergamot	2½ „
„ Neroli Super	40 minims.
Benzoic Acid	2 drachms.

Pure Spirit, sufficient to make four pints.

In this, as well as in all the following extracts, before adding the last portion of the spirit, replace as much of it with water as the perfume will bear without becoming milky, which will vary from two to eight ounces or more. This addition will make the perfume softer.

Moss Rose.

Otto Rose, Virgin	2 drachms.
„ Santal. Flav	2 „
Ext. Musk	12 ounces.
„ Vanilla	4 „
„ Orris	2 „
„ Jasmin	4 „
Benzoic Acid	1 drachm.

Pure Spirit, sufficient to make four pints.

White Rose.

Otto Rose, Virgin	2 drachms.
„ Red Cedar Wood, *true*	6 minims.
„ Patchouli	4 „
„ Orange, *fresh*	½ drachm.
Ext. Tuberose	2 ounces.
„ Orris	2 „
„ Jasmin	2 „
„ Musk	2 „
Benzoic Acid	1 drachm.

Pure Spirit (to which four ounces of rose-water has been added), sufficient to make four pints.

Victoria.

Otto Rose, Virgin	2 drachms.
„ Neroli, Super	2 „
„ Bergamot	4 „
„ Coriander	16 minims.
„ Pimento	24 „
„ Lavender (English)	16
Ext. Jasmin	2 ounces.
„ Orris	16 „
„ Musk	2 „
Benzoic Acid	2 drachms.

Pure Spirit, sufficient to make four pints.

Ess. Bouquet.

Ext. Musk	4 ounces.
„ Tuberose	2 „
Otto Rose, Virgin	1 drachm.
„ Bergamot	1½ „
„ Neroli Super	½ „
„ Verbena, *true*	8 minims.
„ Pimento	10 „
„ Patchouli	3 „
„ Red Cedar Wood, *true*	½ drachm.
„ Lavender, English	12 minims.

Pure Spirit, sufficient to make four pints.

Musk.

Ext. Musk	1 pint.
„ Orris	6 ounces.
„ Vanilla	2 „
„ Styrax	2 drachms.
Otto Santal. Flav	1 drachm.
„ Bergamot	2 drachms.
„ Neroli Super	10 minims.

THE MODIFICATIONS PRODUCED BY LIGHT AND HEAT IN ELÆOMARGARIC ACID.*

BY M. CLOEZ.

Elæomargaric acid is the name given by the author to a solid fatty acid, fusing at 41°, separated from the crystalline salt obtained by saponifying with alcoholic solution of potash the oil expressed from the seeds of *Elæococca vernicia.* The oil yields about 72 per cent. of its weight of this acid. The acid exists in the oil in combination with glycerine, as trielæomargarin, a liquid neutral immediate principle having the curious property of solidifying under the influence of light, without any change in its elementary composition or neutral state.

Elæomargaric acid is a superior homologue of sorbic, linoelic, and palmitolic acids, its place being between the last and stearolic acid, obtained by the action of potash upon bromated oleic acid. Its composition, when prepared without exposure to air and dried in a current of hydrogen at 110°, is represented by the formula $C_{17}H_{30}O_2$. It is a non-saturated body, rapidly oxidizable by air at the ordinary temperature.

Solutions of elæomargaric acid in ether and carbon bisulphide can be preserved indefinitely in the dark and sheltered from air. When exposed to the light the acid is modified, but remains dissolved. Upon distilling off the solvent in a current of hydrogen, the residue consists of the modified acid fusing at 71°, mixed with a very small quantity of a liquid fatty acid that is produced under other conditions in a state of purity. In an alcoholic solution of elæomargaric acid, saturated in the cold, this transformation takes place very rapidly under the influence of light, the tube eventually becoming filled with magnificent lamellar crystals. To obtain the crystals pure they should be rapidly pressed between several folds of paper and removed from the action of air, traces of alcohol or water being driven off by heating them to 110° in a current of dry hydrogen.

The new acid, which the author calls elæostearic acid, has the same elementary composition as elæomargaric acid, but differs from it in the fusing point being 23° higher and in being much less soluble in cold alcohol. It is found in the state of glyceride in oil of elæococca concentrated in the sun or by the action of carbon bisulphide or sulphydric acid. It appears to be the result of the polymerization of the elæomargaric acid.

Upon heating these two solid acids to 175° or 180° in sealed tubes containing hydrogen, nitrogen or carbonic acid gas, they were converted into a liquid modification apparently without either absorption or separation taking place. Elementary analysis confirmed the fact of the transformation of these two isomerous solid acids into a third liquid acid having the same composition

This third acid is named by the author elæolic acid, and it is the acid referred to as present with the elæostearic acid formed by the exposure of elæomargaric acid to the light. It is also found among the products of saponification of oil of elæococca oil that has solidified in the sun. These experiments explain, the author considers, the curious properties that have been observed in elæococcae oil. See before, p. 2.

THE ACTIVE PRINCIPLE OF STROPHANTUS HISPIDUS.*

BY E. HARDY AND N. GALLOIS.

In a paper read before the French Academy of Sciences the authors announce the isolation of two crystalline principles from the seeds of *Strophantus hispidus,* DC., or Inée, an apocynaceous plant, used in tropical Africa as an arrow poison.

The seeds deprived of their hairs were powdered and macerated in alcohol slightly acidulated by hydrochloric acid, the alcoholic tincture filtered and evaporated to the consistence of an extract in a water-bath and then treated with cold distilled water. The solution, left to evaporate spontaneously, yielded white shining crystals that were purified by a second crystallization.

The crystals were soluble in cold water, more soluble in hot water, and only slightly or not soluble in alcohol and chloroform. The crystalline body contained no nitrogen and presented none of the reactions of the vegetable alkaloids, the aqueous solution not being precipitated by iodide of mercury and potassium, iodized iodide of potassium, iodide of cadmium and potassium, phosphomolybdic acid, chloride of gold or chloride of platinum. Neither did the aqueous solution, after being heated with a small quantity of sulphuric acid, reduce the double tartrate of copper and potassium, indicating that the new body was not a glucoside. Pending further chemical studies of this body the authors adopt for it the name "strophantine," which had been suggested for it by Dr. Frazer, who anticipated that it would prove to be an alkaloid. This body possessed considerable toxic power, quickly causing cessation of the heart's action when injected into a frog.

The tufts of hairs removed from the seeds were submitted to similar treatment, and also yielded a crystalline substance; this presented the reactions of an alkaloid, but did not possess the same physiological properties as strophantine, as a considerable quantity injected into the foot of a frog did not stop the movements of the heart. The authors have named this substance "ineine."

PHENICATED CAMPHOR.†

The preparation which has been introduced by Dr. Soulez under this name is a simple solution of 2½ parts of camphor in 1 part of carbolic acid. The liquid thus obtained is pale yellow, of an oleaginous consistency, and smells slightly of camphor without any admixture of the carbolic odour. Phenicated camphor is insoluble in water, in glycerine and in alcohol; but it dissolves in all proportions in the fat oils (olive and almond), and readily emulsifies with water containing saponin.

This preparation is recommended by Dr. Soulez as a preventive of fermentation in dressings for wounds. The dressings are steeped in a mixture of 10 parts of phenicated camphor and 200 parts of olive oil, or one of 10 parts of phenicated camphor and 200 parts of infusion of saponaria. The infusion may be prepared by pouring 1000 parts of boiling water upon 100 parts of saponaria leaves. Dr. Soulez, however, prefers to make a tincture by macerating 250 grams of *Quillaia saponaria* bark for ten days in a litre of 90° alcohol. This tincture, mixed with its weight of phenicated camphor, forms a concentrated emulsion, which is diluted with ten parts of water when required for use.

Advertisements, and payments for Copies of the Journal, to MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE GLORIOUS UNCERTAINTY OF LAW.

WHEN the Lord Chief Justice of England and Mr. Justice HAWKINS concur in laying down a point of law, the layman would need to be a very bold, and even presumptuous man, who would challenge their decision. In commenting briefly upon a case reported on another page, therefore, we distinctly disclaim any intention of challenging the correctness of the ruling; we only point to it as analogous to the class of problems which caused Lord DUNDREARY so much perplexity.

At the Bodmin assizes a man was charged with giving to a girl two figs into which he had introduced a "poison called cantharides, with the intent to injure, aggrieve, or annoy" her. The act was not disputed, but the commission of a statutable offence was disputed. The evidence only deposed to the detection of a grain and a half of cantharides, this being the quantity found in one fig after it had been lying about for some time, the second fig not being examined. It was contended, and successfully, too, that as twenty-four grains would be required for a fatal dose, so small a quantity as a grain and a half, whatever might be the motive of its administration, would not be sufficient to produce the effect desired, and that therefore it was not, legally speaking, a "noxious thing." The Lord Chief Justice held that "there must be a distinction between a thing only "noxious when given in excess, and thing which "is a recognized poison, and is known to be a thing "noxious and pernicious in its effect. A distinction "is to be made between poisons, such as prussic acid "and strychnine, poisons of a well-known and established character, and a thing which is only capable "of doing mischief when administered in excess."

Passing by the fact that prussic acid and strychnia are both administered beneficially as medicines as well as, but much more frequently than, cantharides, and that they too only become capable of doing mischief when administered in excess, we venture to ask a question that in our opinion quite justifies our allusion to the subject in these columns. What constitutes a "recognized poison?" So far as we know, the only poisons recognized formally by law are those included in schedule A. under the provisions of the Pharmacy Act, 1868, in Part 1 of which prussic acid, strychnia and cantharides stand side by side. We are therefore bound to confess that we fail to see the ground of the subtle distinction drawn by the Lord Chief Justice between them, and almost feel tempted to suggest that perhaps the items in the poison schedule were not just then present to his mind. However this may be, it was a fortunate thing for the poisoner that the point of law wae raised, for probably the jury, not being troubled with such niceties of definition, would have come to the conclusion that in administering the alleged non-noxious quantity he was guilty of the "*intent* to injure, aggrieve, and annoy," and after all that was what he appears to have been charged with.

GREEN PEAS AND COPPER.

IT is generally understood that the preserved peas which have more than once brought their vendors in this country within the clutches of the Sale of Food and Drugs Act, because of the copper they contain, have had their origin in France. It will therefore not be inappropriate, considering the different opinions that have been expressed as to them in our own police courts, to hear what is said about them in their native land.

The occasion was a discussion started in the French Academy by General MORIN, upon certain falsifications or alterations of alimentary substances, during which that officer denounced the prevalent colouring of wines with fuchsine and certain articles of food with salts of copper as an injurious fraud. In this condemnation he received the support of the celebrated chemist, M. DUMAS.

It then transpired that the Council of Hygiene for the department of the Seine had requested M. PASTEUR to investigate the subject and ascertain to what extent salts of copper are used to colour preserved peas. From the report which that gentleman is about to make, it appears that of fourteen samples bought in various parts of Paris, ten of them contained copper, some of them to the extent of one-thousandth part of the entire weight of the preserves after the liquor had been drained off. The liquor also contained some copper when any was found in the peas, but in smaller proportion. This copper appeared to be fixed in an insoluble form in the solid matter of the peas, especially under the exterior cortical envelope. The presence of the copper was easily detected even by the eye in every case, by the colour resembling the green of fresh peas, the preserved peas from which copper was absent having always a yellowish tint. In fact, no method is at present known by which peas can be preserved of a green colour without the addition of a salt of copper.

M. PASTEUR is of opinion that even if experimental physiology should prove copper to be less poisonous than has hitherto been supposed, its use in the treatment of preserved foods ought no less to be absolutely prohibited. He would have the name preserved peas represent only the natural product from which copper is absent, and he would not tolerate the sale of coloured peas unless they were labelled, "preserved peas coloured green by salts of copper." Under these conditions tolerance and prohibition might be ranked as synonymous terms, for it is probable that even the greediest gourmand would dispense with his favourite dish rather than have it under such a questionable name.

ANOTHER NEW LOCAL ASSOCIATION.

As every movement that brings chemists and druggists more into friendly intercourse with each other must tend towards the elevation of the trade, we are glad to learn that a new local association has been formed at Blackburn, called the Blackburn Chemists and Druggists' Association, having for its object the better scientific instruction of the assistants and apprentices of chemists and druggists, the protection, general advancement and mutual improvement of its members, and the formation of a library and a museum. We hope that the new association will meet with a full measure of success in attaining these objects, and that especially the courses of lectures and classes which it is proposed to organize will be well supported by the younger members who have yet to pass their examinations.

THE SPONTANEOUS GENERATION DISPUTE.

THE question whether under any known conditions the spontaneous generation of living beings can take place has been the subject of so many diametrically opposed assertions during the past few years, that the discussion seemed fast drifting into the ridiculous. As, however, an attempt at least is now to be made to decide one phase of the dispute between two of the foremost combatants, M. PASTEUR and Dr. BASTIAN, it may be interesting to indicate the points to be dealt with.

According to Dr. BASTIAN if urine carefully deprived of every organic germ be exactly neutralized with liquor potassæ and exposed to a temperature of 50° C. certain forms of bacteria promptly appear in the liquor. M. PASTEUR repeated this experiment, with the exception that he used fused potash instead of solution of potash, and the mixture remained sterile, the inference being that the germs were introduced with the liquor potassæ. He therefore expressed his opinion that it was not accurate for Dr. BASTIAN to say that he had discovered the physicochemical conditions necessary for the spontaneous generation of bacteria. Dr. BASTIAN replied that in using solid potash M. PASTEUR had departed needlessly from the conditions of the experiment, and that as a strong solution of potash in suitable quantity could be easily heated to 110° C. in a closed glass tube there was no necessity for the substitution. Dr. BASTIAN looked upon it as incredible that a fluid so caustic as the strong liquor potassæ he had employed could contain living germs after being heated at 110° C. Further he asserted that M. PASTEUR had added too much potash and rendered the liquid alkaline.

The next step was on the part of M. PASTEUR and was a "defiance" to Dr. BASTIAN to produce fermentation in sterile urine, under the stated condition, in the presence of competent judges, provided only that pure potash and pure water, free from organic matter, should be used in the preparation of the solution, or, if otherwise, that the solution should be previously heated to 110° C. for twenty minutes, or to 130° C. for five minutes. This challenge Dr. BASTIAN at once accepted, with the remark that he had already repeated his experiments under conditions even more severe than those proposed by M. PASTEUR, having used liquor potassæ that had been previously heated to 110° C. for sixty hours, instead of twenty minutes, and that in twenty-four to forty eight hours the urine was in full fermentation and swarmed with bacteria.

At the request of M. PASTEUR, the French Academy of Sciences, before whom the latter part of the discussion had taken place, has appointed a commission, consisting of Messrs. DUMAS, MILNE-EDWARDS, and BOUSSINGAULT, to express an opinion upon the point under dispute between Dr. BASTIAN and M. PASTEUR. Notwithstanding the scientific eminence of the members of the commission, however, it is open to doubt how far they will succeed in convincing either of these able antagonists against his will.

THE CONVERSAZIONE.

WE are requested to say in reference to the Society's Conversazione, that the decision arrived at by the Council, was that cards of invitation should be sent to all Members of the Society and Associates in business.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A MEETING of the above Association will be held at 17, Bloomsbury Square, on Thursday evening next, March 22nd, at eight o'clock, when a paper will be read by Mr. A. P. LUFF, F.C.S., on "The Common Metals and their Chief Uses."

MR. LOUIS SIEBOLD has requested us to express to the members of the British Pharmaceutical Conference his great regret at the long delay in the publication of the 'Year-Book of Pharmacy,' which, he says, has been caused by frequent illness and the consequent accumulation of his engagements. He wishes it to be distinctly understood that he alone is responsible for the delay.

MR. OSWALD A. READE, Pharmaceutical Chemist, has been appointed Dispenser in Charge of Stores in the Royal Naval Hospital, Bermuda.

Transactions of the Pharmaceutical Society.

NORTH BRITISH BRANCH.

The fifth meeting of the present session was held in the Society's Rooms, 119A, George Street, Edinburgh, on the evening of Thursday, 1st March. Mr. Wm. Gilmour, President of the Branch presided and briefly introduced to the meeting Dr. Andrew Wilson, who delivered a very interesting lecture on "A Study of some Lower Animals."

Dr. Wilson prefaced his lecture by expressing the pleasure it afforded him to address the Society. He proceeded to say that the tendencies of the present age have in many cases an injurious and limiting influence on mental work, and he would endeavour to carry out his promise to lecture that evening by directing the attention of the audience to some points in the organization of lower animals which had a bearing on the mental and physical affairs of man himself. It was, in fact, a valuable feature in natural history studies that, in seemingly unimportant studies, the mind was led towards subjects of high import and interest. The following is an abstract of the lecture.

A Study of Some Lower Animals.

BY DR. ANDREW WILSON, F.R.P.S.E.

Lecturer on Natural History, Edinburgh Medical School, and Examiner in Medicine, University of Glasgow.

In stagnant pools a little animal, the *Hydra*, was found in plenty in the summer months. The length of this little body was about one quarter of an inch. It was coloured green, and consisted of a tubular body, rooted by one extremity and possessing at the other or free end a mouth surrounded by tentacles. An examination of this body showed a very simple structure. The tissues of the body consisted of two layers, the outer named the *ectoderm* and the inner the *endoderm*. These tissues formed the walls of the hydra's body, which could be compared to nothing liker than a simple tube, the interior of the tube or body being destitute of any organs such as are found in higher animals. Microscopic examination of the hydra's body showed that the tissues possessed peculiar stinging-cells or thread-cells, each consisting of a tough outer capsule containing a fluid and a coiled up filament. When such a cell was irritated, it ruptured, and the fluid and filament were everted and discharged upon minute animals so as to cause paralysis or death. Stinging-cells of larger size and greater power were noted to form the stinging organs of jelly fishes and similar forms.

That the hydra was a sensitive being was proved by its shifting its position on a glass tumbler so as to come round to the side next the light, and when touched or irritated in any way, the animal contracted both body and tentacles. Food captured by the tentacles was conveyed to the mouth and digested within the simple interior of the body, in the absence of a stomach-sac. The investigation of the manner in which an animal or plant provided for the wants of its individual life, Dr. Wilson remarked, did not by any means complete a naturalist's duties. Death is continually busy in the ranks of animal and plant life, and the biologist has also to note how the losses of individuals are repaired—just as he noted how each individual repairs its own personal losses by nutrition. The hydra was seen to reproduce its kind in three ways. It could be artificially divided, longitudinally or transversely, and from each portion into which it was cut a new hydra would in due time be produced. Trembley, of Geneva, in 1744, first made known to the world the wonderful reparative powers of these animals. The lecturer described in detail his own experiments on these animals, and also on the nearly allied sea anemones, the latter beings also exhibiting a great fertility of reproductive powers, after being cut and divided. The second mode of reproduction noted in hydra was that of "budding" or "gemmation." Veritable buds grew in the warmer months of the year from the sides of the parent hydra, these buds gradually developing into forms resembling the parent. Sooner or later, however, these buds dropped off from the parent organism, each floating away through the water to begin life on its own account. The study of the great group of zoophytes was shown to be greatly facilitated by the investigation of hydra, inasmuch as these beings consist simply of colonies of animals aggregated together in the most intimate manner. They have further been produced originally from a single being, which differed from hydra in that its buds remained connected together in a permanent manner to form the plant-like zoophyte. In describing the history of the zoophyte, Dr. Wilson remarked the interesting nature of the co-operative principle exhibited by these forms. Co-operation in man's affairs, owing to the frailties and weaknesses of human nature, could hardly be carried out to perfection; but in the zoophytes we had an excellent example of the harmonious co-operation of many similar beings to one end—the nutrition and support of the colony. The hydra was also shown to exhibit the common phase of reproduction among animals, in that it produced eggs, from which, through a stated process of development, new beings like the parent were in due time evolved.

Proceeding, by way of application of these remarks, to note a few points of general interest in the life history of animals, Dr. Wilson first directed attention to the "automatic doctrine" of animal organisms. No one could doubt that the acts of a hydra were purely automatic. It acted simply as it was acted upon. It could by no stretch of the imagination be conceived to possess any intelligent appreciation of the why and wherefore of its acts. Many higher animals were in a like position. In the acts of a bee, wasp or ant, wonderfully intelligent as their acts might appear, we had simply an exhibition of *excito-motor* or automatic movements. This was proved to us by the fact that the young insect, just liberated from its chrysalis, entered at once upon and performed all its duties with a perfection and regularity unsurpassed by the adult and fully grown insect. There was thus exemplified a thorough reaction between the animal and its surroundings; but the thoroughness of that relationship did not imply an intelligent appreciation on the part of the insect of the meaning or bearing of its life-acts. In man we had many examples of automatic actions, but in the human subject and in his nearest allies we had to take into consideration the fact that out of the human experience and habit had arisen a new element—consciousness or the knowledge of self, and in the possession of this power of understanding the why and wherefore of their actions, the higher animals differed essentially from their lower neighbours. The development of an infant's mind and intellect might possibly indicate to us, as by a panoramic picture, the stages through which man's intellectual powers had become evolved from lower phases of nervous action.

Remarking that in sea-anemones and hydra no nervous system could be detected, the lecturer said that we could understand the exhibition of nervous powers in such organisms, and also explain the irritability of such plants as the venus' flytrap and sensitive plant, on the supposition that these animals and plants possessed a diffused power of appreciating sensations. This power might in fact be regarded as existing in an unspecialized state in the tissues, and it was probable that all animals and plants possessed this power, although in very varying degrees of development.

The powers possessed by many lower animals of reproducing lost parts were explained under the simile of comparing the hydra and its neighbours to animal "republics," whilst the higher animals in which such powers were undeveloped might be regarded as "limited monarchies." In the theoretical republic every man was as good as his neighbour, although, the lecturer remarked, he did not think this principle of equality could be so perfectly carried out in the human as in the lower phases of life. Thus, one part being as good as any other part in hydra, each part was endowed with great reproductive powers. In the limited monarchy, equality was not a distinctive feature. Some parts assumed precedence of others, and hence in higher animals a breach of continuity so broke up and destroyed the relations of closely connected parts that perfect repair was impossible.

At the conclusion of a very interesting lecture, Dr. Wilson said that his remarks that evening might by many be deemed as leading them very far from the sphere of pharmaceutical studies and from the professional avocations in which his hearers were engaged. It appeared, however, to him that the crowning glory of any learned and intelligent body of men, united for the advancement of their common science, was to be found in their frank and hearty recognition of other branches of scientific inquiry. Recognizing the grand principle that the prosperity of any single science meant the advance of all, he rejoiced to find that the liberal spirit influencing the North British Branch of the Society had ever been illustrated by their encouragement and appreciation of the views and opinions of other scientists. He esteemed it therefore no small compliment to be asked to address the Society, and he would fain hope that in virtue of the interest which the Society evinced in science at large, the subject he had selected as his topic for that evening, although far removed from pharmaceutical matters, had found a certain measure of acceptance with his hearers. The cultivation of natural science studies presented a powerful means for extending and bracing those powers of observation and research which lie at the foundation of scientific advance of every kind; and if he had succeeded in arousing an interest in fields of observation which possess large claims upon human sympathy and regard, he should assuredly feel that his labours of that evening had not been in vain.

Dr. Wilson illustrated his lecture very fully by diagrams.

On the motion of Mr. J. R. Young, a hearty vote of thanks was accorded to the doctor for his very interesting lecture.

The Honorary Secretary intimated the following contributions to the library:—'Proceedings of the American Pharmaceutical Association for 1876,' per John M. Maisch, Philadelphia; 'Pharmacy in its Sanitary Relations,' by John M. Maisch, from the author; the *Canadian Pharmaceutical Journal* for February, from the Ontario College of Pharmacy; The *Pharmacist* for February, from the Chicago College of Pharmacy.

To the museum:—Specimens of the metal Sodium, Cinnabar, Mispickel and Stibnite, from Mr. David Brown, to complete the collection left by his father.

Provincial Transactions.

LIVERPOOL CHEMISTS' ASSOCIATION.

The ninth general meeting was held at the Royal Institution, February 15, 1877; the President, Mr. A. H. Mason, F.C.S., in the chair. The minutes of the previous meeting were read and confirmed.

The following donations were announced to the library:—Current numbers of the *Pharmaceutical Journal*, from the Society; and a copy of the 'Quinology of the East Indian Plantation,' by J. E. Howard, F.R.S., from Mr. Abraham.

The President moved, "That a special vote of thanks be given to Mr. John Abraham, for his liberal donation." This was seconded by Mr. Haddock, and carried unanimously.

Mr. T. L. J. Hughes was elected a member.

The President asked if the tests reported upon by Mr. T. Garside, F.C.S., at the previous meeting, could be applied to the detection of fusel oil in naphtha, the latter substance being often adulterated with fusel oil. He also called attention to Dr. Paul's method of testing quinine, published in the *Pharmaceutical Journal*.

Messrs. A. C. Abraham, Michael Conroy, A. Haddock, and others, entered into a discussion on these points. Other miscellaneous communications having been received, the Hon. Secretary read the following paper:—

A Preliminary Account of some Comparative Analyses, showing Results obtained by Different Processes and their Ultimate Bearings. Part I.

BY THOMAS WILLIAMS, F.C.S.

The study and practice of the science of chemical analysis is more or less an intimate subject to the members of this Association.

The measure of cultivation the field of chemical analysis receives determines the number and value of new substances produced in the arts and manufactures.

The utility of chemical quantitative analysis is of first importance for the aid which it gives to the progress of original research. Another function which it performs is the determination of the chemical value of natural produce, and of products of manufactories.

I propose to limit my subject on this occasion to copper analysis.

It is satisfactory to note that the cultivation of processes for the estimation of copper has not been neglected. I shall give a brief description of methods that are at present in general use. Probably the oldest method (under some improvements in the *modus operandi*) is the Cornish assay: this continues to be extensively practised at the present day. The results which it gives, however, are, from an analytical point of view, universally condemned as being widely erroneous; it never reports the true amount of metal contained in the substance under operation. One of the chief causes operating the loss sustained is due to volatilization of copper in the presence of sodium chloride, which is an ingredient largely employed in the assay. The process consists of three distinct stages, viz.:

1st. Fusion for regulus.
2nd. Calcination of regulus.
3rd. Refining of regulus.

In the first operation the ore is mixed with a flux composed of lime, fluorspar, borax, and salt, with a careful addition of nitre, and fused in a clay crucible. This produces the regulus which in the second stage is finally pulverized and thoroughly calcined to expel the sulphur. The oxides obtained are in the third process reduced at a high temperature with admixture of argol, nitre, borax, and salt. This fusion yields a crude button of metal which has to undergo three or four repeated fusions with a refining flux composed of argol 1 part, nitre 1 part, and salt 2 parts; and the resulting button of metal after this treatment consists of fine copper. By this rough description of the Cornish assay you will see that it is not an uninteresting process, and it illustrates, moreover, the metallurgy on a miniature scale of the principal operations in the Welsh process of copper smelting. But whatever useful purpose it can serve to one class of miners or smelters, who deal with cupreous substances of high produce, it must fail entirely to give any assistance to another class who have extensive transactions daily in the copper industry in low-produce material. The *Chemical News* of January 19, 1877, notes the interesting fact that the Alderley Edge Copper Mines, though producing an ore which by the Cornish assay yields nothing at all, have paid dividends to the extent of nearly £40,000.

I shall leave it with you to say whether, if Mr. Kingzett had performed his investigations on the brain in a Cornish crucible, we should have heard anything about copper in the interesting lecture which he delivered to us.

We had last session a detailed account from Mr. E. W. Parnell, F.C.S., in his paper on "Electricity applied to Analytical Chemistry," of a method of a highly scientific value for the estimation of copper, which he had seen performed on an extensive scale at the Government Mining Establishment, at Mansfeld, Eisleben. That method consisting of, 1st. Roasting the ore. 2nd. Its solution and separation of insoluble matter. 3rd. The precipitation of the copper in the presence of either free sulphuric or nitric acid by means of a galvanic current; and finally weighing the result as metallic copper. This elegant process has received only a limited application in this country; so far, though, its results are indisputed. One explanation for it not being more adopted, probably, is due to the impression that battery power is not so easily kept ready for action as a supply of cyanide of potassium solution, to the use of which we are so long accustomed.

The volumetric estimation of copper by means of a standardized solution of potassium cyanide was invented over a quarter of a century ago, and has been since that period in general use in different parts of the world.

This method depends upon the action of potassium cyanide on an ammoniacal solution of copper, the azure blue colour of which is discharged by the formation of a double cyanide of copper and ammonium and separation of free potash, while one equivalent of cyanogen is separated, which, acting on the free ammonia, gives urea, oxalate of urea, cyanide of ammonium, and formiate of ammonium.

It is a well-known fact, however, in practice, that the decomposition is uncertain, the quantity and degree of concentration of the ammonia salts producing a very appreciable variation in the results. Towards remedying this uncertainty, Fleck's modification of the process has proved itself to yield more reliable results, but still they are only approximate in character. By Fleck's process, a solution of sesquicarbonate of ammonia, one in ten, is employed instead of the caustic ammonia; the assay is heated to a temperature of 60° C., and in order to render the end reaction plainer he proposed the addition of two drops of solution of ferrocyanide of potassium, one in twenty; the addition of which should not affect the assay, but at the point when the blue colour is discharged by the potassium cyanide the characteristic red-coloured ferrocyanide of copper becomes visible; and on the addition of a final drop of the standard (KCy) solution, the red colour in its turn vanishes, leaving the assay entirely colourless. Fresenius states that he finds that the presence of ammonia salts are here also not without influence, and remarks that on this account the method seems to be applicable only if the standardizing of the cyanide of potassium solution and the actual analysis are performed under a very similar circumstance.

In May, 1867, the directors of the Mansfeld Copper Mines, Germany, offered an award of £45 for a process of assay to estimate copper in ores produced at their mines. Out of sixteen answers which they received, Dr. Steinbeck's method was adjudged the most suitable. A premium was given also to Luckow for his plan, which consisted finally in precipitating the copper by means of a galvanic current and weighing in the metallic state.

Dr. Steinbeck's process consists of, 1st. That the copper contained in the sample (of which 5 grammes is taken) be brought to a state of solution in hydrochloric acid. 2nd. The insoluble matter having been separated by filtration, the copper is precipitated in the metallic state in a covered beaker-glass of about 400 cubic centimetres capacity by means of a rod of metallic zinc weighing about 50 grammes, to which is fastened a stout piece of platinum foil (the zinc and platinum having at the onset been placed in the beaker); the precipitation is effected in from half to three quarters of an hour, when the zinc rod is removed, leaving the platinum foil in the beaker; the spongy copper is thoroughly washed by decantation with water. 3rd. The estimation of the precipitated copper. This is effected by dissolving the copper in a *definite quantity* of nitric acid, diluting a *definite quantity* of ammonia added, and finally titration with standard potassium cyanide solution.

Fresenius observes that the results given by this method are not only concordant, but also very nearly correct, if the cyanide *is standardized under the same condition as it is used.*

In standardizing, as nearly as possible the same quantity of copper should be employed as will have to be estimated. The strength of the cyanide solution employed being 1 c.c. = ·005 gramme metallic copper. To what extent Dr. Steinbeck's masterly application of the cyanide process is followed in this country I am not able to say, but I have a strong impression that it is not so widely adopted as its advantages over the results obtained in the ordinary unreliable way warrant. I will here show one or two results obtained by different processes. A carefully prepared sample (No. 1) was apportioned and sent to four different professional analysts to be tested for copper:—

Chemist A returned the produce by the cyanide of potassium process . . .	6·30	per cent.
Chemist B returned the produce by the cyanide of potassium process . . .	6·28	„ „
Chemist C by Dr. Steinbeck's process .	5·60	„ „
„ D by Luckow's galvanic precipitation of metallic copper . . .	5·38	„ „
Sample No. 2.		
Chemist A, cyanide potassium process	0·32	„ „
„ B, „ „ „ .	0·28	„ „
„ C, Dr. Steinbeck's process .	0·16	„ „

I could produce further comparisons on samples of about ten times the richness of sample No. 1, where differences amounting to 2 per cent. have occurred. Can there be any reasonable objection to adopting Dr. Steinbeck's process for general use in all laboratories where the cyanide process is practised? I may answer for myself that though I do not find it convenient in every case to determine copper by Steinbeck's method, I certainly never trust cyanide under the old system.

To any one who would prefer some other process not referred to this evening, I beg to contribute my testimony to the accuracy of results obtained by the gravimetric subsulphide process. This method, first recorded by Berzelius, and afterwards by Brunner, has of late received a very practical application from the apparatus introduced by Rose.

The value of this process is based on the strong affinity which copper and sulphur have to combine either in the dry state or in solutions. The subsulphide process may be conveniently divided into three stages, viz.:

1st. The solution of the cupreous substance in nitric acid, addition of sulphuric acid, evaporation to dryness, and separation of insoluble matter by filtration and washing (preferably with dilute H_2SO_4).

2nd. The precipitation of the copper in the filtrate by sulphuretted hydrogen gas, and collection of the copper sulphide on filter paper, thorough washing with water containing a little H_2S, and drying.

3rd. The ignition of the dried sulphide with a slight addition of sulphur in a current of dry hydrogen gas, and weighing.

The precision with which copper can be estimated by this process is as accurate, if not more so, than any other process on record. If time permitted, I might produce abundant proofs of this from results of a great number of experiments that I have performed in this direction during the last twelve months. To attain success the conditions must be rigorously attended to, and the certainty of the results are nothing short of the perfection of the combining weights assigned to the copper and sulphur.

It is well known that whatever process is adopted to determine the chemical value of a substance for copper, that difficulties often arise with the presence of certain other metals that have to be overcome, but I presume we all agree that the best process is that which yields the greatest returns, so long as they are strictly to be relied on and express the *chemically pure* substance.

An interesting discussion followed, and, on the motion of Mr. Haddock, seconded by Mr. A. C. Abraham, a cordial vote of thanks was given to Mr. Williams for his paper.

The tenth general meeting was held at the Royal Institution, March 1; the President, Mr. A. H. Mason, F.C.S., in the chair.

The minutes of the previous meeting were read and confirmed. The President read a letter which he had received from Mr. E. W. Parnell, F.C.S., stating his inability to be present to read his paper "On the Separation of Iron and Alumina," and would be glad to read the same the earliest opportunity that could be afforded him.

It was decided to announce Mr. Parnell's paper for Tuesday evening, the 27th inst.

The President called attention to the number of deaths which took place from the accidental drinking of carbolic acid. He said that hardly a week passed over without some person being poisoned by drinking it in mistake for something else, and this generally arose in consequence of its being kept, when obtained for disinfecting purposes, in beer bottles. He suggested that in order to guard against those accidents, the acid should be sold in a particular description of bottle, or that carbolic powder, which was most convenient for use, and would not be attended with the dangers of the acid, should be used for disinfecting.

Mr. E. Davies, F.C.S., said that much of the powder sold was very poor in quality, some containing not more than one fourth or one fifth of the strength of the acid, and therefore its efficacy for the purpose required would be very slight. He thought that the sale of carbolic acid should be surrounded with as many precautions as any other poison.

Mr. James T. Armstrong, F.C.S., exhibited an ingenious apparatus invented by Dr. Mills, of Glasgow, the chief purpose of which is for ascertaining the colours of different liquors required to be compared for commercial purposes.

The thanks of the meeting having been given to the authors of the various miscellaneous communications, the members adjourned.

CHEMISTS AND DRUGGISTS' TRADE ASSOCIATION.

A meeting of the Executive Committee was held at the office of the Association, 23, Burlington Chambers, New Street, Birmingham, on the 28th February, 1877, at 1 p.m. The President in the chair; Mr. Thomas Barclay, Vice-President.

Present:—Messrs. Andrews (London), Arblaster (Birmingham), Churchill (Birmingham), Cross (Shrewsbury), Fairlie (Glasgow), Greaves (Chesterfield), Holdsworth (Birmingham), Jervis (Sheffield), Johnson (Manchester), Laird (Dundee), Shaw (Liverpool), Southall (Birmingham), G. Walker (Coventry), R. Walker (Birmingham), and the Solicitor of the Association.

The minutes of the previous meeting of the Executive Committee and of the meetings of the Finance and Law Committees were read and approved.

Reports from the Finance and Law Committees were then read, and resolutions passed ordering them to be received, adopted and entered on the minutes.

In answer to the President, the Solicitor said with regard to the Runcorn milk of sulphur case, the court would open for the spring quarter sessions at Knutsford, on Easter Monday, when the appeal would be heard, and it had been arranged that the Salford milk of sulphur cases should stand adjourned until after this appeal; it would then be for the committee to decide what course should be taken in the Salford cases. He further stated that he had personally investigated the case of a member residing at Nottingham, who had been summoned by the Master and Warden of the Apothecaries' Company of London, for the penalty of £20 for prescribing, and that as far as he could ascertain the case was clearly that of simple "counter prescribing;" it would be heard at the Nottingham county court on the 13th of March.

The arrangement of a time and place for the annual meeting of the Association was fully discussed, when it was moved by Mr. Andrews, seconded by Mr. Jervis, and unanimously resolved: "That the Annual Meeting of the Association be held in London on Tuesday, the 15th of May, and that the following gentlemen be appointed a sub-committee to make further arrangements:—The London members of the Executive Committee, Messrs. Howden, Humpage, John Owen, Postans, Urwick, and J. H. Wright, with power to add to their number."

Mr. Greaves said the election for the Council of the Pharmaceutical Society was approaching, and he thought it would be a great advantage to the members of the Society if all candidates would make known their views. He thought as a rule a majority of the members voted in the dark, he would therefore move: "That in the opinion of this Committee it is desirable that all candidates offering themselves for seats on the Pharmaceutical Council should publish their views, so that members of the Society may have an opportunity of voting for such candidates as would advance their interests."

Mr. Jervis quite agreed with Mr. Greaves that members of the Society should know something of the politics of the candidates for whom they voted.

Mr. Churchill seconded the resolution, which was passed *nem. con.*

Mr. Fairlie said, that in accordance with the desire of the Executive, a scheme for Scotland had been drawn up by the sub-committee appointed for that purpose, and that bye-laws had also been framed, a copy of which was on the table.

After some discussion, it was moved by Mr. Fairlie, seconded by Mr. Greaves, and unanimously resolved: "That the clauses of the scheme and bye-laws now proposed to the Executive Committee be considered *seriatim.*"

The scheme and bye-laws having been gone through minutely, and the various details carefully considered, and in some instances amended, it was moved by Mr. Southall, seconded by Mr. G. Walker, and unanimously resolved: "That the amended scheme and bye-laws of the Scotch Committee of the Chemists and Druggists' Trade Association—here following—be and are hereby approved of."

Bye-Laws of the Scotch Committee of the Chemists and Druggists' Trade Association.

1st.—That this Committee shall be called "The Scotch Committee of the Chemists and Druggists' Trade Association."

2nd.—It shall consist of eighteen members of the Association, five to form a quorum, selected from the various districts as set forth in the scheme for Scotland, three of whom shall be recommended for election as members of the Executive, and all of whom shall be recommended for election as members of the General Committee of the Association. Any district failing to elect a member, the vacancy shall be filled up by the Executive.

3rd.—It shall meet as occasion may require, and shall, at its first meeting, appoint a president, vice-president, and honorary secretary; it shall also nominate three of its number to be members of the Executive.

4th.—Its duties shall be to aid the Executive in conducting the affairs of the Association in Scotland, with the assistance of a Scotch solicitor, appointed by the Committee, and subject to the approval of the Executive; and it shall prepare and submit annually to the Executive a report of its proceedings during the year.

5th.—The rules of the Association shall be binding on the Committee.

6th.—It shall not incur expenses exceeding the amount of £10 sterling per annum, without the sanction of the Executive or that of the Finance Committee of the Association.

7th.—The Committee shall have power to convene a meeting of the Scotch members of the Association for purposes connected with the Association, and shall do so at the request in writing of any seven members of the Committee; ten clear days' notice of which shall be given by circular to each member in Scotland, by the Hon. Secretary of the Committee.

8th.—These bye-laws shall not be altered or rescinded unless with the consent of the Executive of the Association, and no motion of change shall be entertained, unless such proposal has appeared on the agenda of business.

SCHEME FOR SCOTLAND.

	Counties in District.	Estimated Number of Chemists in Districts.	Principal Town in District.	Number of Representatives on General Committee.
1	Kinross, Clackmann, Fife	29	Dunfermline	1
2	Haddington, Linlithgow, Edinburgh	140	Edinburgh	3
3	Berwick, Peebles, Selkirk, Roxburgh	33	Galashiels	1
4	Dumfries, Kirkcudbright, Wigton	40	Dumfries	1
5	Stirling, Dumbarton, Lanark, Renfrew, Ayr, Bute, Argyle	350	Glasgow	5
6	Perth	27	Perth	1
7	Forfar	60	Dundee	2
8	Kincardine, Aberdeen	75	Aberdeen	2
9	Banff, Elgin, Nairn	30	Elgin	1
10	Ross, Cromarty, Inverness and Western Islands, Caithness, Sutherland and Northern Islands	40	Inverness	1

The Secretary reported that he had canvassed the town of Leeds, Bradford, Sheffield, Wolverhampton, Stourbridge, Manchester, Stockport, Runcorn, Rochdale, Carlisle, Newcastle-on-Tyne, and Gateshead, in which towns he obtained about 330 new members, and donations slightly in excess of his travelling and hotel expenses. He obtained about fifty other members in Edinburgh and Liverpool, when addressing meetings there during the last few weeks; time did not permit his canvassing these towns. He would submit to the notice of the Committee that although he had been absent from the office about six weeks altogether, a considerable portion of his time had been employed in arranging public meetings of the trade, replying to correspondence forwarded to him from the office, and some little time in collecting evidence of illegal trading under the Pharmacy Act 1868.

The best means of electing the General Committee was debated, when it was moved by Mr. Barclay, seconded by Mr. Andrews, and unanimously resolved: "That no steps be taken to elect a General Committee until after the annual meeting of the Association in May."

Several letters were read from persons complaining of illegal trading, and the Secretary was instructed to continue to gather evidence on the subject.

A vote of thanks to the President for presiding terminated the proceedings.

THE ASSOCIATION OF CHEMISTS AND DRUGGISTS FOR WOLVERHAMPTON AND DISTRICT.

A meeting of this Association was held in the committee-room in the Agricultural Hall, on Thursday evening, March 8th. The chair was taken by Mr. Fleeming, the President of the society.

The Chairman stated that the meeting had been called to consider the desirability of having classes formed entirely among themselves, and the selection of a new room, as the one they now occupied would have to be given up at Midsummer next. He expressed his disappointment that so few apprentices were present, as it was entirely for their benefit that the institution was kept up, and the necessity for close application to their books was becoming more evident every day. He earnestly invited them to make good use of the means offered them, so that the council might feel recompensed for the trouble they had taken in the matter.

Mr. Brevitt (Honorary Secretary) strongly recommended the apprentices to attend the classes that were being conducted at the Free Library, and at one or two other places in the town. There were many reasons why he advised this, the chief being that there would be greater decorum at those classes than there had been in one of the classes conducted by themselves. Studious apprentices had complained to him about the disorder, and it was impossible that any good could be done or any knowledge obtained unless order prevailed. He felt sure that would be the case at the Free Library classes, as he expected that some of those who attended would be of riper years. With respect to the rooms, he offered a room he had in Darlington Street, and explained how the students would be much benefited thereby. He proposed their assembling once a week, and the students having free access to the Materia Medica specimens, as well as the plates and books. One of the council would attend and offer them any advice when they needed it, and also register the books lent.

Messrs. Coleman, Cannell, Lowe, and others expressed their approval of this suggestion, and eventually a resolution was passed authorizing its adoption, at the same time expressing thanks to Mr. Brevitt for his offer.

Mr. Cooley was elected co-secretary in the room of Mr. F. J. Barrett, F.C.S., who now holds an appointment at Coventry.

Mr. Brevitt also read a letter from Mr. Southall, Birmingham, who had kindly undertaken the adjudication of the Essay prizes. After complimenting the authors of the four essays generally, he decided as under:—

First Prize . . . . Mr. W. B. Cooley.
Second „ . . . . Mr. Fletcher.
Third „ . . . . Mr. Watts.

The programme for the prizes at Christmas next will be issued shortly. The thanks of the meeting to Mr. Fleeming for presiding concluded the proceedings.

LEICESTER CHEMISTS' ASSISTANTS AND APPRENTICES' ASSOCIATION.

A lecture was delivered at the rooms of the above Association on Tuesday evening, March 6, by Mr. Walter Clark; the subject being "Chlorine, Bromine, and Iodine." There was a good attendance of the members, and special interest and attention exhibited.

After a brief introduction by the President, Mr. W. Hammond, the lecturer proceeded to state that he did not purpose treating the different elements separately, but would take their respective peculiarities, properties, and differences together, thereby rendering the lecture more interesting, and as he (the lecturer) thought enabling the hearers better to retain the various facts advanced. The years in which these elements were discovered and by whom, together with their sources, were first referred to; after which at considerable length the lecturer pointed out their physical characteristics, solubility, density, etc. The processes of their preparation and the decompositions which occur during the necessary operations were also made clear. The various chemical tests necessary for the detection of impurities in these elements were also pointed out.

At the close of the lecture a vote of thanks, proposed by Mr. Raynor, to Mr. Clark for his able and instructive lecture was carried unanimously.

Proceedings of Scientific Societies.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A meeting of the above Association was held at 17, Bloomsbury Square, on Thursday evening, March 8th, Mr. Harold Senier in the chair, when a paper on "Fermentation" was read by Mr. G. F. Gutheridge.

The author commenced by explaining what was ordinarily understood by the term "Fermentation," and then proceeded to point out its relations to putrefaction, decay, and various catalytic actions, remarking that the confusion that existed with regard to the application of the term was probably due to the number of different theories held upon the subject. He then showed that fermentation differed essentially from putrefaction and decay, in the fact that in the former process no offensive odour was present, and the product formed was of a useful nature, whereas in the latter noxious gases, such as sulphuretted and phosphoretted hydrogen, were evolved. Reference was then made to the various kinds of fermentation, which received distinctive names from the products formed in each case, and certain essential conditions of temperature, etc., were noticed, which were the same in all cases. He then passed on to consider in detail the more important of the many varieties of fermentation, beginning with the alcoholic or vinous, as being the chief. After describing this, and explaining that it was due to the development and growth of a peculiar fungus, known as the "Torula cerevisiæ," a specimen of which was exhibited under the microscope, he pointed out the various theories held, notably those of Pasteur and Liebig, regarding the action of this fungus in inducing the process of fermentation. He then went on to treat of the acetous, lactous, and saccharine fermentations, noticing the various conditions under which each took place, and concluded by briefly referring to some of the less important kinds, as the gallous, the amygdalous, and the mucous varieties.

The paper gave rise to an interesting discussion, at the close of which, on the motion of Mr. J. Edward Owen, a vote of thanks to the author was unanimously passed.

The President, having announced miscellaneous business, an election of officers to fill some vacancies that had lately occurred then took place. Mr. Charles H. Hutchinson was elected Vice-President in the room of Mr. H. Campbell, resigned; and Messrs. W. R. Atkins and H. G. Greenish were elected members of the Committee in place of Messrs. J. C. Shenstone and C. H. Hutchinson resigned. The meeting then adjourned.

Parliamentary and Law Proceedings.

PROSECUTION OF A CHEMIST AND DRUGGIST UNDER THE APOTHECARIES ACT.

At the Nottingham County Court, on Tuesday, the 13th inst., before Mr. Wildman, Judge, Mr. George Shepperley, chemist and druggist, Long Row, Nottingham, was sued by the Apothecaries' Company, for having acted as an apothecary, he being unqualified so to do. Mr. Arthur Browne represented the plaintiffs, and the defendant was represented by Mr. Buszard, Q.C., instructed by Mr. Glaisyer for the Chemists and Druggists' Trade Association.

Mr. Browne stated that the action had been brought under the Act of George III., chap. 194, as follows:—"And be it enacted that any person (excepting such as are then actually practising as such) who shall after the first day of August, 1815, act or practise as an apothecary in any part of England or Wales, without having obtained such certificate aforesaid, every person so offending shall upon every such offence forfeit and pay the sum of £20."

His Honour did not consider it necessary to hear a statement of the facts from advocates, consequently Mr. Browne called

Mr. George Shepperley, who said: I am a chemist and druggist, carrying on business on the Long Row, having conducted the business on my own account for nine years. I was in business before that. I was assistant in the same shop along with my predecessor and father, Mr. James Shepperley. Previously to that I was dispenser at the General Hospital. I am not a qualified apothecary. I know a person of the name of Hubbard, at all events I know him by sight. I recollect him coming on the 4th December last to my shop. He asked me for something to cure pimples in the face which I noticed he was afflicted with. I did not examine him with a view to ascertain what he had the matter. I will not swear that he did not go behind the screen, but I believe he did not. The screen and counter are attached. I cannot well remember now, but I know I stood behind. I cannot recollect what the medicine was that I gave unless I see the bottle. It might be medicine to be taken internally, or it might be a lotion. The bottle produced is no doubt the one that I gave, but I am not sure, though the label is very much like those which I use at times. I cannot say from memory what was the kind of medicine I gave, but for pimples I often give sarsaparilla. I usually charge tenpence or a shilling a bottle, but I could not say what I charged in this instance. I only remember Hubbard coming once. He was a perfect stranger to me. The medicine was not given for a particular disease—it was a simple medicine. I know a Mrs. Cooper, wife of William Cooper, of Radford, and I believe she has been to my shop, but I have no very distinct recollection. I believe she had some gallic acid from me, but I do not known whether that would lead me to know from what disease she suffered. I asked her what she wanted it for, and she said it was because she had too much monthly weakness. She asked me if I thought that was the right stuff to take, and I said it was. I mixed it up with plenty of water, and, in fact, in the usual way of mixing the acid. Before she asked for the acid I do not think she told me what she was suffering from. She asked me to mix it properly, so I put another kind of acid, which is usual. This was in August, 1876. She came again several times, in fact she was a regular customer. I cannot say whether, when she came again, she said whether the medicine had done her good or not. Subsequently to the visit I allude to she has not told me what she has been suffering from. Though I keep no entries in my books, I know this was gallic acid, as Mrs. Cooper has told me so.

I saw her a week ago; in fact I called upon her to ask what she came to me for. I did that in consequence of my having received a notice about an action being brought against me. I did not call to ask her not to give evidence against me; I will positively swear I did not. I know a woman named Elizabeth Moore, whom I saw some years ago. I recollect seeing her about the beginning of January. She had some one with her. I believe it was her sister in-law, Mrs. Burton. When Miss Moore came she wished to rest in my shop, as she complained of a pain in the head. I did not examine her in any way. I did not take her into a private room, neither did she go there. She merely sat down in the shop. I am quite sure on that occasion I did not give her any medicine. She has not been since; she was a regular customer, but I cannot say what she asked me for when she came. I swear that I never used an instrument to her, though I keep such things for sale. I never use such a thing as a stethescope. I supplied her with drugs generally, but I cannot say what she had in particular. She generally complained of pain in the head. I think she never brought me a prescription.

His Honour: She may have had drugs, but not medicine.

Witness continued: I believe she has had medicine at my shop, but not of my giving. I have had Mrs. Burton at my shop, and dispensed a prescription of Dr. Burnie, a local physician. A Mrs. Osborne has been to my shop.

Mr. Buszard, Q.C., here contended that in the case of Osborne the twenty-one days' notice had not been given as required by the 30th section of the Apothecaries Act.

Mr. Browne expressed an opinion that the Act did not apply to such cases as this, but really to the entire case, and not of different cases which cropped up in the whole action.

His Honour agreed with Mr. Browne, and overruled Mr. Buszard's objection.

Mr. Buszard, however, still held that Mr. Browne had no right to call such evidence without proper notice having been given, as the Act defines the matter very definitely, when it says that for ever such offence he shall be liable to a penalty.

His Honour allowed plaintiffs to continue their case.

Mr. Browne: Do you know a Mr. Death? Yes. (Laughter.)

Mr. Browne: I do not know what the laughter should be for.

His Honour: I really do not know what there is about Death to provoke laughter, except for the fact that in this instance it is Jolly Death.

Examination continued: I have a very indistinct recollection of Mr. Death's presence in August last. I do however remember seeing him in the Talbot Vaults, as a neighbour of mine had told me Death was watching my shop. I went to the Talbot to ask him if it were true. He said he was not. He told me what the law was in reference to prosecution. He said then that before that night he had been to my shop and I prescribed for him. I have an indistinct recollection of Death having called at my shop, when I looked at his throat. I cannot say what I did but certainly if he asked me I should have looked and supplied him with medicine. I think he did not bring a prescription. I cannot say what I gave him, whether he asked for any medicine, or what I charged him. When at the the Talbot I did not say I refused to prescribe, but I know I have at times refused to prescribe. Though I have refused at times to prescribe I have consented to prescribe on other occasions. My age is 45 years.

By Mr. Buszard: I have been in the habit of giving simple remedies for simple complaints. When people have come to me suffering from disease or serious complaints I have invariably sent them to a physician. I recollect very little about Mr. Death or Mrs. Cooper. I make up thousands of prescriptions every year. I have known Miss Moore and her father for years.

Re-examined by Mr. Browne: I cannot say how I judge of sample medicines. The prescriptions I make up are medical men's prescriptions.

Thomas Jolly Death said: I recollect going to Mr. Shepperley's shop on the 22nd of August last. Mr. Shepperley was there behind the counter. I said, I want some medicine for relief of sore throat, cold, tightness of the chest.

His Lordship: A complication I suppose.

Witness: Mr. Shepperley then told me to face the light that he might look down my throat.

His Honour: Had you asked him to look at your throat?—No.

Witness: He tapped me in the chest and said, "The tightness is there, I suppose."—I said, Yes. He then said "I think I can give you something for there does not seem to be much amiss with you."

His Honour: I suppose in point of fact there was not much amiss?

Witness: He gave me some medicine to take internally and I paid a shilling. I asked him how much and his reply was, "One shilling, please. I think you'll find relief from that; if not come again." That was all that passed. I did not take the medicine. I saw Mr. Shepperley again. It was in the Talbot. Mr. Shepperley said, "I believe you are Mr. Death." I said, "That is my name." He said, "Being a nervous man I was at first alarmed, but I took counsel amongst my friends and I have decided to go on prescribing." After attending a woman who had a bad leg he said, "I have been prescribing, still prescribe, and mean to continue. If you go on we shall fight the question and if you win we shall make an appeal."

His Honour: Then we may take it that he said he had prescribed, was prescribing, and should go on so doing?

Witness: I have seen many people go into Mr. Shepperley's shop, but I cannot say whether they had not prescriptions.

By Mr. Buszard: I was not engaged in what I call continued watching, but I have been employed to take this matter in hand.

Mr. Buszard:—You do a large business in this way, I suppose.

Witness: I have been at it about fifteen years.

By Mr. Buszard: It was in November when I saw him at the Talbot Vaults. I do not know whether I really asked him first to look at my throat.

Mary Cooper, wife of William Cooper, living at Radford, said in answer to Mr. Browne: I recollect going to Mr. Shepperley's shop at the latter end of August last. I saw him in the shop, and, in accordance with my complaint, I asked for some gallic acid and seidlitz powders. He supplied me. I asked him if he thought it would do me good, but he did not advise me to take it. However I said I should like to try it. He did not say what would do me good. I went to him again several times, and had the same kind of stuff.

Mr. Browne: You went at other times?

His Honour: Unless you can carry it further than this it does not matter if she went 500,000,000 times.

This being the whole of the evidence,

Mr. Buszard contended that his Honour ought not to give judgment for plaintiffs, as the defendant had done no more than was the practice before and since 1815, when the Apothecaries Act passed, which was to prevent the chemists from visiting patients as doctors.

His Honour said if defendant had done no more than a druggist usually does over the counter as a dispenser, he could not find for plaintiff. Though several witnesses had been called, the real point at issue was that spoken to by Death, as the other witnesses had broken down; and if Death's evidence had stood alone, he should have hesitated about convicting upon it, but then it was to some extent borne out by the evidence of Shepperley himself.

Mr. Buszard said then he must rely on the 28th section, which gave chemists power to prepare, compound, dispense and vend, and he contended Mr. Shepperley had done no more.

His Honour, however, told the learned counsel that the defendant had done considerably more than that.

Mr. Buszard continued that it was the practice before 1815 and since for chemists and druggists to prescribe for simple ailments, and the Act of that year was never intended to diminish that custom. The Act did not define what an apothecary was.

His Honour observed that the case went further than that, for, according to the evidence, a man went, complained of cold, tightness at the throat, and defendant prescribes for him as a medical man.

Mr. Buszard: How is that acting as an apothecary?

His Honour: Then are we to suppose acting as an apothecary is cutting off a man's arm?

Mr. Buszard: It is a question as to the definition of the term dispensing.

His Honour said he should be quite contented if his definition of the term were overruled by the Supreme Court.

Mr. Buszard then called Thomas William Parsons, who said he lived at Swithland, and was 84 years of age. He was apprenticed to Messrs. Blews, chemists and druggists, of Worcester, in 1809, and from there he went to a London firm of chemists, finally setting up in business in Leicester on his own account. He said that when he first went into the trade it was the custom of chemists and druggists to prescribe over the counter for persons who suffered from sore throats, or ailments of that kind.

His Honour: That was before the passing of this Act. (To Witness): What do you understand dispensing means? —Mixing up medicines.

His Honour: Upon prescription?—Yes: and sometimes without a prescription. His Honour put several questions to the witness as to what he considered to be the meaning of the word prescription.

Mr. Buszard: He is eighty-four years of age, your Honour.

His Honour: Well, I am not much younger.

Mr. Buszard said it seemed to him that the intention of the Act under which these proceedings were taken was in no way to diminish the business of the chemists and druggists as it existed before the Act. He admitted that the visiting and attending of patients was prohibited by the Act, and cited a similar case heard before Judge Heath, in 1849, and reported in the *Pharmaceutical Journal*, where the charge was one of attendance upon patients at their own households. In that case the judge said a single act did not of necessity imply the adoption of a business or calling, and held that a chemist might administer a dose of medicine for a sore throat or a complaint of that kind without being liable to a charge of practising as an apothecary. He (the learned counsel), submitted that attending patients meant something more than giving a man a prescription for a sore throat or headache. The only right he contended for, was that of counter practice, which would not be included in the word dispense.

His Honour: As to the word dispense, that is really a question for a superior court.

Mr. Buszard then called

Mr. John Horne Glaisyer, who said he was assistant in the shop of Messrs. Glaisyer and Kemp, at Brighton, 1876. If persons came into the shop for something for a sore throat or headache, it was the custom to give them something to relieve the complaint.

After hearing the evidence his Honour gave judgment for the amount claimed, (£20) and also gave leave for an appeal, Mr. Buszard having intimated that the case would be taken to a superior court.—*Nottingham Journal*.

ALLEGED ATTEMPT TO POISON.—IMPORTANT RULING.

At Cornwall Lent Assizes on Wednesday, March 7, before the Lord Chief Justice, Sir A. Cockburn, William Hannah was charged with administering to Mary Ann Rowe a poison called cantharides, with intent to injure, aggrieve, or annoy, at Mevagissey, on the 21st October, 1876. Mr. St. Aubyn prosecuted and Mr. Carter defended. On the day in question the prosecutrix and defendant had some conversation together in the street, after which the defendant gave the prosecutrix two broad-figs. On getting home she was proceeding to eat them when her father detected something glistening in them, and he at once ordered her to throw the figs away. It was then found that what was glistening was cantharides. A few days afterwards the defendant came to her house and told her father that he intended the figs containing cantharides for a girl named Robins, and asked for forgiveness, but Mr. St. Aubyn contended that whether it was intended for this person or anybody else the prisoner would still be guilty of attempting to annoy by means of a noxious drug. In reply to Mr. Carter, the prosecutrix's father said he did not know at the time what the nature of Spanish fly was, but he was suspicious of what appeared to be glittering, and he made subsequent inquiries.

P. C. Brown produced the fig in question, which was handed over to him by the last witness.

Mr. G. Mitchell, chemist, St. Austell, examined the fig, and found it to contain Spanish fly, weighing from a grain to a grain and a half, a quantity insufficent to produce any effect upon the human system. According to Dr. Taylor cantharides would not produce the effect popularly supposed unless it was given in sufficient quantity to produce death.—In cross-examination, witness said there were other flies besides the Spanish fly that had the appearance of the one now produced. A fatal dose would amount to about 24 grains.

Mr. Carter contended that to sustain the indictment it must be shown that there had been a sufficient quantity of the drug administered to cause the effect alleged to be desired, so that, whatever the intent was, it would not in law amount to administering a noxious thing if what was administered could produce no effect.

His Lordship observed that one of the most deadly poisons that a murderer could resort to was strychnine, yet it was used as a medicine by the most eminent practitioners. A man might administer strychnine, thinking he would produce a destructive effect, but he might only use that quantity which a medical man would say would do no harm, still he used a noxious thing for producing a certain effect.

Mr. Carter, continuing his argument, said in many little *bon bons* made by confectioners for children, prussic acid was used, and although prussic acid was a most deadly poison, yet it was used in such small quantity as to be perfectly innocuous.

His Lordship could not help thinking, that, supposing the thing was not capable of doing mischief, if it were used for the purpose of doing mischief, then the person administering it must take the consequences. There were three points for consideration. Did the prisoner administer the thing? Was it a noxious thing? Or was it administered, being a noxious thing, with the intent to injure or annoy?

Mr. Carter submitted that there must be both the power and the intent to injure, basing his remark upon a former ruling of his lordship's, when he held that, in order to find a man guilty of pocket-picking, it must be proved that there was something in the pocket, and that the prisoner put his hand there.

His Lordship consulted his learned brother, Mr. Justice Hawkins on the points raised, and on returning into Court said:—

My learned brother and I have given this case great attention. We feel it is a question of considerable importance, and we are of opinion that Mr. Carter's point is a good one; and that the prisoner must be acquitted. The statute requires, in order to constitute an offence, that there shall have been the administration of a noxious thing, and we think in order to make out an offence, the thing administered must be of such a character as to satisfy rigorously the requirements of the law, namely, that it must be a noxious thing. I think there must be a distinction between a thing only noxious when given in excess, and a thing which is a recognized poison, and is known to be a thing noxious and pernicious in its effect. A distinction is to be made between poisons, such as prussic acid and strychnine—poisons of a well-known and established character, and a thing which is only capable of doing mischief when it is administered in excess. Upon the medical evidence before us cantharides, or, as it is commonly called, Spanish fly, is administered medicinally, and in small quantities, and up to a certain extent it is incapable of producing any effect at all. What is important to the present case is that the quantity administered was incapable of producing any effect. The statute makes it an offence to administer, although not with the intention of taking life, but of doing any serious bodily harm, any noxious thing with intent to cause injury or annoyance, but unless the thing is a noxious thing in the quantity administered, it seems exceedingly difficult to logically say there has been a noxious thing administered. The thing is not noxious in the form in which it has been taken; it is not noxious in the degree or quantity in which it has been given and taken. We think, therefore, that the indictment will not hold. It would be a very different thing if the thing administered, as regards either its character or degree, were capable of doing mischief, but because it happens to fail in a particular instance from some collateral or unforeseen cause, owing, may be, to the vigour of the constitution of the person to whom it was administered, or some cause of that description, if it was capable of doing mischief it would not be within the statute. But here the quantity was incapable of doing any mischief, and, therefore, we shall not be justified, although it was administered with the intent of producing inconvenience or annoyance, in saying that it is within the statute, seeing the thing is not, in the form administered, noxious. Therefore, under those circumstances, the case is not made out against the prisoner, and you are bound to find him not guilty.

The prisoner was accordingly acquitted, and discharged with a caution to be careful for the future.

The Herbarium Prize.

Sir,—Mr. F. J. Hanbury's able criticism of the regulations under which the above prize is offered, recalls to my mind an interesting conversation I had with the late Mr. D. Hanbury at the very evening meeting when Mr. F. J. Hanbury's own splendid Herbarium was exhibited and the medal it so justly deserved presented. Mr. D. Hanbury when asked if he did not consider the limit of age too narrow, acknowledged that the subject was one worthy of further consideration, and the prize regulations capable of improvement. Seeing that Mr. F. J. Hanbury's collection was so far above the standard usually reached, it is highly gratifying to find him opening up a scheme for increasing the popularity and usefulness of this competition.

Would it not, however, be far better to divide this competition into two classes, the one open to students of the Society only, age limit from 15 to 21, the other for members and associates, age limit from 21 to 25?

In this manner the younger men would not be open to the competition of the more advanced students of botany, whilst a few clauses in the regulations requiring at least a certain number of specimens (say 600) and such like restrictions, would give a tone of superiority to this higher grade of the competition.

I think there could be little difficulty in carrying out this scheme, a scheme at any rate less expensive than Professor Bentley's liberal suggestion offered at the meeting before alluded to, recommending "that in different centres, covering say an area of twenty miles, prizes might be offered for the best collection of British plants."

Nor need expense stand in the way, for I am sure, in the event of the Council shrinking from the annual outlay such a modification would entail, there must be many gentlemen who would be willing to subscribe a sufficient sum to cover any cost of medals, etc., aiding, as it assuredly would, the advancement of the study of botany amongst their younger *confrères*.

In conclusion I hope Mr. Hanbury's suggestions will receive from the Council the attention they deserve, and so be the means of increasing the usefulness of one of the best competitions connected with our Society.

John Herbert Wilson.

Pharmaceutical Chemists and Coroners' Inquests.

Sir,—Referring to the discussion at the last Council meeting, I wish to say that I know from experience that it is not at all uncommon for a pharmaceutical chemist to be summoned to serve on a jury, and that being so, he must attend at the time and place appointed. But by presenting a certified copy of the register to the presiding judge or coroner he can get released, because there are always more persons summoned than are really wanted, to provide for emergencies; not only so, but I find that coroners are yearly supplied with the calendar by the Secretary. Some time ago we were all advised to get a certified copy of the register of our own name from Bloomsbury Square, which could be done on payment of one shilling. It was on a small piece of paper and I pasted mine in the volume of the Journal that contains a copy of the Juries Act, so that by taking this book I was armed with all that was necessary to free me.

But what I wish more particularly to say is, that there is some little difficulty in keeping one's name off the list of persons liable to serve. When pharmaceutical chemists were first exempted, I, as local secretary for this town, was requested to see the vestry clerk and supply a list of pharmaceutical chemists, which I did, and saw the names erased from the official list. My surprise can therefore be imagined on being summoned not long after, but it was to serve on a grand jury for the Borough Sessions; this I found was a separate list altogether, in fact a sort of burgess list which had nothing to do with the county. I caused all our names to be crossed off this list and then I thought I was really free. But no, some two years later I received another precious document, and this was because I found it necessary to live away from business, and the house happened to be in an adjoining parish, and so my name had got on the county list in another parish. Since then, however, all has gone on well; but even now, if the various officers who compile these lists were to leave and fresh people be appointed, I should not at all be surprised if our names were put on again. It is about Easter when these lists are being made up, and it behoves all local secretaries to be on the alert both in town and country at that period, for it is a great nuisance to have to waste one's time and for which there is no recompense.

William Yates Brevitt.

Wolverhampton.

Borax as an Antiseptic.

Sir,—At the evening meeting of the Pharmaceutical Society held on March 7th, Mr. Robottom, in his very interesting remarks on the discovery of borax in Southern California, related a very remarkable and somewhat romantic incident. Travelling on one occasion, weary and unwell, across the bed of what had been at some former period, a vast salt lake, and from which "some hundreds of tons" of native borax are now dug out and obtained, he saw in his pathway the dead body of a horse, and upon it, with but little hesitation, sat himself down to rest. The sun was shining fiercely, and the water he was carrying was hot and unfit to drink. He, however, bathed his temples from the vessel containing it and felt refreshed. Then, with his mind bent on discovery, he commenced a *post-mortem* on the body of the horse. To his astonishment, though the temperature around him was almost too high for endurance, he found that no decomposition had taken place, but that on the contrary, the flesh, as such, was in a perfectly sound and good condition. On inquiry he was *told* that the carcase had been lying on the bed of borax, which was immediately underneath it, during the whole of the previous six months. Thereupon Mr. Robottom arrived at the conclusion, and it may be said very naturally so, that the borax had been instrumental in preserving the flesh, and in entirely preventing those putrefactive changes which under ordinary circumstances would inevitably have set in. Now if this were really the case the discovery would be of much value. For an account of some excellent experiments showing the effect of borax on substances readily capable of fermentation and putrefaction I would refer to a paper by J. B. Schnetzler (*Comptes Rendus*, lxxx., 473, *Pharmaceutical Journal*, 3rd series, v., 846), inserted in the 'Year-Book of Pharmacy' for 1875, page 332. Though, in these experiments, "Beaf, veal, and portions of sheeps' brain," were *wholly immersed* in a concentrated solution of borax, the result was not completely successful. There was no putrefaction, but the meat "had an odour *sui generis*." In the case, however, of the dead horse, not only had the borax kept intact the part with which it was immediately in contact, but, inferentially, the whole carcase had been brought successfully under its preservative influence. It is difficult to acquiesce in a conclusion such as this. Borax, in fact, possesses no such power. As an antiseptic it is inferior to boracic acid, whilst boracic acid must yield in turn to carbolic and benzoic acids. And yet meat will putrefy in an atmosphere of the latter though entirely cut off from contact with the outer air. How then, in the present instance, is the preservation of the body of the horse under a burning sun to be accounted for? Presuming the statement of Mr. Robottom's informant to be correct, it would seem to point to the probable truth of the germ theory. It is not impossible that in the wild and untrodden regions of Southern California, beyond and around the Sierra Nevada, the atmosphere, from its extreme and almost optical purity, together with its excessive dryness, causing particles of saline matter from the surface deposits to diffuse themselves through it, might be found incapable of propagating germ life. In an atmosphere such as this, decomposition would be slow, and even the experiments of Dr. Bastian might be reduced to *nil*. But, be this as it may, borax can scarcely exercise its antiseptic power except under the condition of actual contact. If it were otherwise, the grand problem of bringing animal food from the distant shores of Australia would be immediately solved. We might well wish for such a result, and it may be ours in time. In the meanwhile, it is instructive to learn the many and various uses to which borax may be advantageously applied, and at the same time deeply interesting to know that, henceforward, it will come to us in comparative purity, and without stint or limit, direct from the newly-discovered saline deposits of the "Far West."

King's College Hospital. W. WILLMOTT.

CASTOR OIL LOZENGES.

Sir,—In the *Pharmaceutical Journal* of Febuary 3, you drew attention to an anonymous letter which appeared in the *Lancet*, in which the writer implied that the so-called "Castor Oil Lozenges" contain a large quantity of calomel. As it is very important that every chemist should know something of the nature of what he is retailing, I write to state that within the last few days two specimens of lozenges have been brought under my notice for analysis. One lozenge was stamped "Castor Oil Lozenge" and purported to be made by a surgeon carrying on a retail business in the East End, and the other was marked "Aperient Lozenge" and was sold by a chemist at Deal. Both lozenges were pink in colour and flavoured with otto of rose, and on analysis proved to contain exactly three grains of calomel each. I am informed that the surgeon is doing a large business, both wholesale and retail in these lozenges.

The above result entirely corroborates the statement of the writer in the *Lancet*, and it is to be hoped that the persons dealing in these lozenges will caution their customers against a too free indulgence in them.

368, *Clapham Road, S.W.* A. RIVERS WILLSON.

HYDROBROMIC ACID BY FOTHERGILL'S PROCESS.

Sir,—When hydrobromic acid is made according to the formula of Dr. Fothergill, published in the last number of this Journal, viz., by adding tartaric acid to a solution of bromide of potassium, not nearly all the resulting bitartrate of potassium is deposited, and the stronger the solution of hydrobromic acid, the more bitartrate is apparently held dissolved thereby. A sample recently examined, containing 6·4 per cent. of acid, left on evaporation 3·7 per cent. of bitartrate. A fluid ounce of a second sample, containing 11·9 per cent. of acid, similarly treated, left 67·9 grains of residue, or about 14 per cent. Other samples examined gave no residue when evaporated, and had either been otherwise made, or if made by Fothergill's process had afterwards been distilled.

Manchester. ALFRED N. PALMER.

THE BRITISH PHARMACOPŒIA.

Sir,—A reprint of the British Pharmacopœia is soon to be published without alteration; but there is at least one which ought to be made, and that is in the strength or name of an Aqua which is peculiarly and dangerously different from all the others. I allude to the Aqua Laurocerasi (which a late mysterious death must recall to the recollection of most of us). The dose of this Aqua is 5 to 30 m., similar to that of Tinct. Opii, and yet it is classified with the Aquæ, the dose of which is in all other cases about ½oz. or more. This extreme difference seems to me not only dangerous but absurd, and I suggest either that the name be changed, or that its strength be reduced to that of the other Aquæ. W. S. CARMICHAEL, M.D.

MILK OF SULPHUR.

Sir,—Is it not time that the uninteresting subject of milk of sulphur was dropped, to give place to some more inviting correspondence? Your correspondent, Mr. Robert Chipperfield, seems big with the importance of the subject, and looks like riding his hobby until he goes up in a "blue flame." It would indeed be a pity if the child of his imagination should hoist him in such a fashion, so please warn him in time so that his services may not be entirely lost to his loving brethren. If the authorities under the Food and Drugs Adulteration Act declared it to be illegal to sell the old well-known popular and valuable preparation of sulphur with lime, as "Milk of Sulphur," there is only one thing to be done and that is to "submit to the law," to the detriment of the public who will no longer get what they have been accustomed to and believe in. If public analysts and common informers—mind I do not class them together—wish for a wider field to display their zeal, there are scores of things which they can pounce upon, of more importance to the public at large, and also injurious, which the old-fashioned milk of sulphur is not.

March 12, 1877. LOYNE CESTRA.

P. D. Streber.—In dispensing copaiba, it matters little whether it be weighed or measured as its specific gravity averages ·950 to 1·000, which would be nearly that of water. As to the best modes of making the emulsion, this depends on the excipient, if liq. potassæ be the excipient it may be emulsified in a bottle; if mucilage, it must be triturated in a mortar; and the result in the latter case is more satisfactory if a little powdered gum arabic be added at the time to thicken the mucilage.

"*Invalid.*"—The eggs may be preserved by packing them with the small end downwards in clean dry salt, in barrels or tubs, and placing them in a cool and dry situation (Cooley).

X. Y. Z.—(who should have sent his name and address). —A successful candidate for a Bell Scholarship must attend the course in the next succeeding session.

"*Lumen.*"—We see nothing in the Regulations to prevent a man presenting himself a second time, provided that he is under the stated age.

"*Syrupus.*"—*Tortula intermedia.*

H. G.—We think troy ounces must be intended.

Y. E.—The so-called egg powders are generally only the ordinary "baking powders" with the addition of a little turmeric or other colouring matter.

GLYCERINUM TRAGACANTHÆ.

BY J. C. THRESH.

Numerous suggestions have at various times been made for improving the pill masses of the Pharmacopœia, or rather such of them as acquire by keeping a consistence unsuitable for rolling into pills. This object it is generally sought to obtain by use of some more suitable excipient, which, without being hygroscopic shall still retain the mass in a plastic and readily diffusible condition. A mucilage of Tragacanth and Glycerine would appear most likely to fulfil these conditions, and has been recommended for the purpose by several pharmacists, but I am not aware that any one has undertaken a series of experiments for practically determining this point. As the subject appeared worthy of consideration I caused to be made, in September last, a series of the official pill masses made according to the official formulæ, and two other series of the same masses made up with Glycerine of Tragacanth.

The Glycerine of Tragacanth used for the two latter series varied in composition, the forms for which I will designate as No. 1 and No. 2.

No. 1—(Proctor's).

Pulv. Tragacanthæ	℥iij
Glycerini	℥ix
Aquæ	℥iv

Mix the gum and glycerine till smooth before adding the water.

No. 2.

Tragacanth. Pulv.	℥iii
Glycerini	℥vj
Aquæ	℥vj

Mix, as above.

The excipients thus prepared form an opaque and not very tenacious mass, but by keeping a few days they become almost transparent and very tenacious. If when the mucilage is being prepared, the whole be placed on the water-bath the same change takes place in a few minutes.

From each of the pill masses a small portion was taken and rolled into pills, and the whole placed in the shop store. Six months having elapsed since the pills were made, the whole have been submitted to examination, with the subjoined results. The references in this table are to the conditions of the masses, as being of suitable or unsuitable consistency for rolling into pills.

Name	B. P.	No. 1.	No. 2.
Pil. Aloes Bbd.	Good	Good	Good
„ „ et Ferri	Hard & brittle	Hard & brittle	Hard & brittle
„ „ et Myrrh	Ditto.	Ditto. (1)	Ditto.
„ Coloc. Co.	Like Stone	Good	Good
„ Cambog. Co.	Not rollable	Too tough	Good
„ Ipecac. Co.	Very good	Good (2)	Good (2)
„ Hyd. Subchl.	Good	Hard (3)	Hard (3)
„ Rhei. Co.	To hard	Good	Good
„ Scillæ Co.	Brittle	Very good	Very good
„ Saponis Co.	Hard (4)	Good	Good

(1).—This mass could be rolled out, though with great difficulty.

(2).—These masses were not, even when first made, as plastic as the B. P.

(3).—These were very hard, but when worked in the mortar formed a very good mass.

(4).—A very good mass when mixed with a little water.

With regard to the two forms of Tragacanth Mucilage, I see no reason for giving the preference to either, since the results obtained are the same, both with regard to consistency of mass when first formed, and after being kept for a length of time.

The following notes taken at the time when the masses were first prepared, may be of service in this inquiry, and as the masses formed by aid of Tragacanth and Glycerine No. 2, differed only from those made with No. 1, in being a little softer, I shall cease to mention them separately.

Pil. Aloes Bbd. (B. P.) A very good mass which rolled well.

Pil. Aloes Bbd. (G. T.) Required only half quantity of G. T., instead of Conserve; rolled well.

Pil. Aloes et Ferri (B. P.) Crumbly mass; rolled out with difficulty.

Pil. Aloes et Ferri (G. T.) 6½ drs. of pill powder made a good mass with 1½ drs. of Tragacanth paste; rolled readily.

Pil. Aloes et Myrrhæ (B. P.) A fairly good mass.

Pil. Aloes et Myrrhæ (G. T.) 3½ drs. of powder took 45 grs. of Tragacanth; the mass rolled well.

Pil. Cambogiæ Co. (B. P.) A good workable mass.

Pil. Cambogiæ Co. (G. T.) 5 drams powder required 1 dram glycerine, making a very good mass.

Pil. Coloc. Co. (B. P.) Tough mass, requiring to be rolled rapidly.

Pil. Coloc. Co. (G. T.) 22 parts of powder took 3⅜ Tragacanth and Glycerine; formed a good plastic mass.

Pil. Hyd. Subchlor. (B. P.) Greasy paint-like mass, rolling fairly well.

Pil. Hyd. Subchlor. (G. T.) 4 drams powder required 1¼ of the mucilage, making a good mass.

Pil. Ipecac. Co. (B. P.) (5 parts powder, 1 treacle.) A very good mass.

Pil. Ipecac. Co. (G. T.) Not so good a mass as the B. P., not being sufficiently adhesive.

Pil. Rhei Co. (B. P.) Very good mass; rolling well.

Pil. Rhei Co. (G. T.) 8½ drams powder took 2½ of excipient, forming a very nice mass.

Pil. Saponis Co. (B. P.) Rolling tolerably well.

Pil. Saponis Co. (G. T.) Opium 1, Sapo 3½, Glycerine of Tragacanth ½, (1 in 5); a very good mass.

Pil. Scillæ Co. (B. P.) Tough, easily worked mass.

Pil. Scillæ Co. (G. T.) Not so good as the official form.

It will be observed that the relative proportion of Tragacanth mucilage required to make up the various powders into a mass depends upon the nature of the powders, but the average proportion of this excipient appears to be 1 to 4. One part equals about 2 of conserve, or 1½ of treacle.

A further and most important consideration is the diffusibility of the pills made by aid of this medium, since an excipient may answer perfectly so far as regards the forming of substances into plastic masses, capable of forming pills which will retain their form, etc., yet if these pills, either have or acquire a condition rendering them difficult of disintegration, this would be an insuperable objection to the use of that excipient. Therefore to ascertain the action of fluids upon the pills made with Glycerine of Tragacanth, and to compare it with the action of the same fluid upon the official pills, a number of the various pills were placed in test tubes, ½ oz. water being added to each. The whole were then placed in a warm place, and occasionally shaken. In most cases the pills made with Tragacanth swelled to about double their original size, and but slightly coloured the water. They also retained their form after a number of hours, even when well shaken, but at once fell to pieces if squeezed with a rod. Some of the official pills, as the Pil. Rhei. Co., readily yielded to the action of water, others as Pil. Coloc. Co. have resisted this action for over thirty-six hours.

These tests are not satisfactory, since the action of the water does not represent the solvent action of the stomach's contents; but when a pill yields to water, there can be no doubt as to its exercising its proper action when taken into the system, whereas in the opposite case, there is necessarily a doubt which can only be cleared away by physiological experiments. I hope, however, by further investigations, to arrive at some more satisfactory results as to the diffusibility and action of pills made with the Tragacanth and Glycerine medium.

Granting, then, for the present, that pills made with this excipient are as active as those made with syrup, treacle or conserve, these experiments appear to justify the following conclusions:—

1st. That Glycerine and Tragacanth is totally useless for keeping the Pil. Aloes et Myrrhæ and Pil. Aloes et Ferri in a plastic condition, but that it makes with the latter a better pill mass (than conserve of roses) for immediate use.

2nd. That for Pil. Ipecac. Co. it is not so good an excipient as treacle. That its advantage in Pil. Hyd. Subchlor. is doubtful. When this pill is first made it is more cleanly, and rolls better, if made with tragacanth than when made with castor oil; and pills of the former kind, when placed in boxes with magnesia, do not acquire the unsightly appearance which the ordinary pills do. In Pil. Sapo. Co. the advantages are also doubtful.

3rd. In Pil. Aloes Bbd. and others of a similar character, the conserve is to be preferred.

4th. In Pil. Coloc. Co., Pil. Cambog. Co., the Glycerine medium answers admirably, and might with advantage be ordered by the Pharmacopœia for that purpose. In Pil. Rhei Co. and Pil. Scillæ Co., it also appears to possess advantages over the official excipients, but I would not take upon myself, without further trials, to recommend its being substituted for them.

On the whole, however, Glycerine and Tragacanth does not answer the expectations, and scarcely bears out the assertions of some who have recommended it. It is undoubtedly a very convenient substance to have upon the dispensing counter, as there are very few combinations which resist its persuasive powers, but it is equally undoubted that there are very few combinations for which an experienced dispenser cannot find a more suitable excipient.

Buxton, March 16, 1876.

COMPARATIVE EXAMINATION OF THE MORE IMPORTANT COMMERCIAL VARIETIES OF GALBANUM AND AMMONIACUM GUMS.*

III. COMPARISON OF GALBANUM WITH AMMONIACUM.

BY EDWARD HIRSCHSOHN.

(*Concluded from page* 712.)

A comparison of the results obtained with these two gum resins shows that quantitative analysis, as illustrated in the tables, gives a means of recognizing the commercial varieties of each gum and their falsifications, whilst the qualitative reactions sharply distinguish the two gum resins from each other. Especially the behaviour of the gum resins towards rectified petroleum furnishes an important test, since petroleum spirit that has been some time in contact with the gum resin should not when heated to 120° C. leave a residue exceeding 1 per cent. of the weight of the resin, otherwise an adulteration is indicated. In the case of galbanum an adulteration with sagapenum might be suspected. Also, the petroleum residue should not contain any sulphur, the presence of which might arise from sagapenum or asafœtida.

As will appear from the tables already given* the portion taken up by petroleum spirit (volatile oil) plus the ether residue (resin) should not in a good sample of Persian galbanum fall under 65 per cent; from the Levant galbanum in granis these residues should be not less than 63 per cent.; from galbanum in massis not under 60 per cent.; from ammoniacum in granis not under 66 per cent., and from ammoniacum in massis not under 55 per cent.

The amount of ash† may also be used in the estimation. From Persian or Levant galbanum in tears it should not exceed 4 per cent., from the Levant in lump not more than 6 per cent., from ammoniacum both in tear and in lump it should not exceed 3 per cent. in a good sample.

As a qualitative reaction to distinguish the varieties of galbanum, hydrochloric acid can be used, as it colours the Persian resin yellow red, passing into red, and the Levant different shades of violet. The petroleum spirit extracts from the Persian sorts gave with nitric acid a rose-red colour; those from the Levant sorts differing shades of violet. Bromine vapour coloured the Persian weakly or intensely violet, but coloured the Levant yellow.

The Persian and African ammoniacum may be distinguished from each other by chloride of lime solution, which colours the Persian orange, but produces no colour with the African.

Persian ammoniacum and galbanum may also be distinguished from each other by chloride of lime solution, which produces no change with any of the galbanums, whilst, as before mentioned, it colours Persian ammoniacum orange. To distinguish African ammoniacum from galbanum the behaviour of the gum resins with sulphuric acid and hydrochloric acid, and of the petroleum extracts with nitric acid and bromine vapour, may be used, as these reagents produce no noteworthy change on African ammoniacum.

Persian and African ammoniacum differ in the melting point of the resin, that of the former being from 40° to 50° C., that if the latter 36° C. An adulteration with olibanum or similar resins may be detected by the melting point, as olibanum does not melt until 75° C. is reached. Also, the ether-resin from all the samples of galbanum, upon boiling with water, gave indications of umbelliferon; this is not the case with Persian ammoniacum, which by similar treatment gave a body resembling phloridzin.

The two gum resins were both found to consist of a volatile oil, various resins, gum, sugar, dextrin, and bassorin like substances; besides which galbanum and African ammoniacum contain umbelliferon, and Persian ammoniacum the phloridzin-like body.

---

* From a memoir for which the gold "Suworow" medal has been awarded by the Medical Faculty of the University of Dorpat. (*Pharmaceutische Zeitschrift für Russland*, April 15, 1875, p. 225.)

* See before, pp. 531 and 711.
† See tables on pp. 430 and 711.

As to the origin of galbanum the author believes, from its varied behaviour with reagents, the different action of the volatile oils upon polarized light, and the different proportions of volatile oil to the gum resin, that it is derived from different plants. He also points out that the Levant galbanum occurring in commerce contains no fruit, and seldom stalks, but always slices of root, whilst the Persian galbanum always contains fruit and stalks.

IV. SAGAPENUM AND OPOPANAX.

Sagapenum.—As sagapenum is used for the adulteration of galbanum, the author included it in his researches. The following were the varieties examined:—

1. Sagapenum, from Bombay, presented to the Dorpat Institute by Professor Henkel. Irregular, moderately soft masses, formed of agglutinated bluish or greenish yellow translucent tears, mixed with rather a large quantity of thin stalk fragments. Smell resembling galbanum. Professor Henkel considered this specimen to be a galbanum, an opinion that was confirmed by the chemical reactions.

2. Sagapenum in massis, from the Dorpat collection. Agglutinated masses of a dirty dark olive-brown to almost black colour, rather soft in the interior; slightly translucent. Contains a little stalk débris, and possesses a strong garlic-like odour.

3. Sagapenum in massis, from the Dorpat collection (occurred in commerce in 1820 to 1830). Greenish white, soft, agglutinated masses, permeated with stalk débris, and smelling like No. 2.

4. Sagapenum electum, from the Lucae collection. Brownish yellow, slightly translucent, tolerably hard lumps, softening between the fingers, having a garlic-like odour, and containing stalk débris.

5. Sagapenum, London, 1873, sent by D. Hanbury to the Dorpat collection. Like No. 3, but formed from tears.

6. Sagapenum in granis, from the Dorpat collection. Various sized, angular or rounded reddish yellow-brown grains, moderately translucent to transparent. Fracture even and dull; easily powdered; smell not so strong as in preceding.

7. Sagapenum in granis, from the Lucae collection. Like No. 6.

8. Sagapenum ordinarium, from the Lucae collection. Similar to No. 5, but the small pieces more translucent.

Upon moistening a small piece with alcohol and treating with concentrated sulphuric acid, all these sorts of sagapenum dissolved with a dark brown colour, the solutions of Nos. 1, 6, 7, and 8 being carmine-red at the edges. Upon adding to these solutions two to three volumes of 95° alcohol, Nos. 2 to 5 formed light brown-red solutions, No. 1 a violet solution, and Nos. 6, 7, and 8 blue-violet solutions passing into blue. Water added to the sulphuric acid solution causes a deposition of a violet body.

Hydrochloric acid added to sagapenum moistened with alcohol gave with Nos. 2 to 5 yellow-red solutions, with Nos. 1, 6, 7, and 8 rose red, passing into violet, which in 6, 7, and 8 changed to blue violet, and finally to blue. By distillation in the vapour of water, No. 3 yielded 7·5 per cent. of a light sulphuretted oil, smelling intensely of garlic, which dissolved with a blood red colour in strong sulphuric acid, and with a blue-green, passing to a blue colour, in a mixture of chloral and chloral hydrate.

The quantitative estimations gave the following results:—

No.	Petroleum Spirit.		Ether.	Alcohol.	Water.	Residue.	Moisture.
	Vol. Oil.	Resin.					
1	5·98	0·3	38·85	3·50	29·23	18·68	3·72
2	13·59	2·30	58·99	2·40	10·74	8·46	3·52
3	12·83	3·57	54·70	2·88	16·85	5·18	2·99
4	16·94	5·10	41·26	3·09	20·37	10·54	2·70
5	10·55	3·68	37·00	2·06	25·61	19·12	2·03
6	9·63	6·26	27.21	3·04	21·42	30·09	2·35
7	7·37	9·20	38·78	3·13	29·00	11·39	1·18
8	7·34	12·86	37·14	2·46	25·95	12·44	1·81

The figures in this table show that the petroleum spirit residues were considerably greater than in any of the ammoniacums and in almost all the galbanums. Only a very few of the latter yielded a greater residue, and that residue was nearly all volatile, whilst the petroleum spirit residues from sagapenum, with the exception of No. 1, consisted of volatile oil and *non-volatile* resinous bodies.

Upon treating the petroleum spirit extracts with a few drops of solution of bromine in ether, a red, passing into violet, turbidity was produced in Nos. 2 to 5, and after a time a violet body changing to blue was deposited (resembling Persian galbanum). Nos. 1, 6, 7, and 8 gave no colour, but possibly there was a separation of a very small quantity of violet body (similar to Levant galbanum). Bromine vapour produced in Nos. 2 to 5 a very intense red-violet colour, passing to blue-violet; whilst in Nos. 1, 6, 7, and 8, only a yellow colour resulted. Frohde's reagent produced in Nos. 6, 7, and 8, first a carmine red colour, which became violet and finally blue; in No. 1 a very faint rose colour; and in Nos. 2 to 5 a yellow colour passing to blue. Hydrochloric acid produced with the petroleum spirit residues from Nos. 2 to 5, yellow-red solutions (similar to Persian galbanum); with Nos. 1, 6, 7, and 8 rose red solutions, which in 6, 7, and 8 passed through violet and blue-violet to blue; but No. 1 showed a redder violet. Chloral and chloral hydrate mixture coloured the residues from Nos. 2 to 5 green (like Persian galbanum), and those from Nos. 1, 6, 7, and 8 rose red to raspberry red, passing to violet (like the older specimens of Levant galbanum).

Upon deflagrating the petroleum spirit and the ether residues with saltpetre and testing for sulphuric acid, the presence of sulphur was recognized in all except No. 1. The residues from the ether extracts behaved exactly like those from galbanum, and also gave upon boiling with water a clear indication of umbelliferon. The alcohol residues behaved exactly like those from galbanum; sugar also was detected in them.

Water took up considerably more from sagapenum than from ammoniacum or galbanum, and the extracts behaved like those before described; they also contained an inactive mucus and a dextrin-like body. The insoluble residue consisted principally of a body resembling bassorin, besides stalk fragments and fruit.

The different behaviour of the sagapenums examined towards reagents indicated that they included two commercial varieties. No. 4 and 5 behaved exactly similar to the undoubted Persian sorts, Nos. 2 and 3, so that, notwithstanding their physical differences, the author is inclined to reckon them as Persian. Nos. 6, 7, and 8 he considers to be Levant sorts. No. 1, from its behaviour with petroleum spirit and reagents, he considers to be galbanum.

It is worthy of remark that in their behaviour towards reagents, Persian sagapenum and Persian galbanum so closely resemble each other, and the same may be said of the behaviour of Levant sagapenum and the older sorts of Levant galbanum.

As characters distinguishing sagapenum from galbanum and ammoniacum, therefore, may be used (1), the presence of sulphur in sagapenum, and (2), their behaviour towards petroleum spirit. Persian sagapenum yielding to it 2 to 5 per cent., and Levant 6 to 12 per cent. of resin, whilst the resinous residue from Persian galbanum amounted at the most to 0·2 to 0·3 per cent., and that from Levant galbanum to 1 per cent.

OPOPANAX.—The samples examined were as follows :—

1. Opopanax, in granis, from the Lucae collection.
2. Opopanax, from a Dorpat pharmacy.
3. Opopanax, in massis amygd. from the Lucae collection.
4. Opopanax, in massis, from the Lucae collection.
5. Opopanax (worm-eaten).
6. Opopanax, from Paris.
7. Opopanax, from the Lens collection.
8. Opopanax, from an old pharmacy.
9. Opopanax, frust. marm., from the Lucae collection.
10, 11, and 12. Opopanax, from the Dorpat collection.

Small pieces treated with alcohol and sulphuric acid gave yellow solutions, which with three times their volumes of alcohol added formed clear light yellow solutions. With hydrochloric acid a light yellow solution resulted. Solution of chloride of lime gave no reaction worth noting.

The quantitative examination gave the following results :—

No.	Petroleum Spirit.		Ether.	Alcohol.	Water.	Residue.	Moisture.
	Vol. Oil.	Resin.					
1	3·27	2·97	38·85	10·39	25·41	16·85	2·76
2	3·11	2·52	26·25	13·63	28·98	27·95	2·56
3	5·97	1·61	29·71	14·95	20·83	25·59	1·84
4	2·86	2·58	24·86	16·06	33·45	17·82	2·26
5	3·07	1·10	14·81	10·08	11·00	57·91	1·43
6	2·06	1·45	22·68	16·66	26·29	29·18	1·68
7	2·06	1·53	30·37	12·10	28·04	29·01	1·89
8	2·06	1·78	31·81	18·91	30·85	18·11	1·53
9	1·04	1·00	23·05	13·50	28·74	32·00	0·67
10	1·25	1·01	25·21	15·46	17·89	37·88	1·30
11	1·65	1·20	20·68	12·13	25·56	36·61	2·17
12	1·36	1·49	28·26	10·86	28·95	30·09	3·99

The petroleum spirit extracts upon heating to 120° C. left an odourless, oily, almost tasteless mass, amounting to 1 to 3 per cent. of the weight of the drug. Treated with strong sulphuric acid this resin dissolved with a yellow colour, which changed after a time to a faint red. Hydrochloric acid, nitric acid, solution of chloride of lime, and chloral and chloral hydrate gave no noteworthy reaction. Tested for sulphur the petroleum spirit residues gave negative results.

The residues from the ether extracts were brittle and dissolved readily in alcohol, the solution giving a plentiful precipitate with alcoholic solution of acetate of lead. Boiled with water the resin gave a faintly yellow intensely bitter liquid, with a strong acid reaction and becoming turbid on cooling; this liquid contained no umbelliferon. Acetate and subacetate of lead and subnitrate of mercury produced in it a plentiful precipitate; perchloride of iron a plentiful greenish grey precipitate. Solution of chloride of lime did not change the colour of this liquid, indicating the absence of a body resembling phloridzin. No umbelliferon was obtained by dry distillation of the resin.

Alcohol (95°) extracted considerably more from opopanax than from galbanum, ammoniacum, or sagapenum, and the residue when treated with water gave a strongly yellow coloured bitter liquid, having an acid reaction. Perchloride and protosulphate of iron gave with this solution a greenish brown precipitate, and more or less coloured precipitates were produced by acetate of lead and subnitrate of mercury. Fehling's solution and ammoniacal silver solution were reduced after gently warming. Solution of gelatine gave no precipitate; therefore neither sugar nor a body resembling gallic acid was present.

The residue from the watery extract behaved like those from the other gum resins, and contained an inactive mucus and a dextrin-like body.

The insoluble residue gave with solution of iodine an intensely blue colour, and consisted principally of stalk fragments.

The almost negative behaviour of sagapenum in the presence of reagents presents, therefore, a means of distinguishing it from the other gum resins referred to. But a more certain character is the proportionally large alcoholic residue that opopanax yields; the maximum from galbanum, ammoniacum, or sagapenum being 4 per cent., whilst the minimum quantity from opopanax is 10 per cent.

THE DETECTION OF ADULTERATIONS OF OLEUM THEOBROMÆ.*

BY GUSTAVUS RAMSPERGER.

In the list of queries of the American Pharmaceutical Association, the following occurs :—There is reason for believing that our oleum theobromæ is largely adulterated. How can the adulterations be detected, and to what extent do they exist?

The answer to this query is somewhat difficult, as there seems to be no perfectly reliable criterion by which to distinguish the adulterated cacao butter from the pure. The statements in the books of reference are conflicting, and differ in essential points. The U. S. Pharmacopœia gives no test for purity, neither does Wood and Bache.

The Pharmacopœa Germanica says: "Sit e subflavo album, odoris exigui proprii, saporis mitis, sebo ovillo rigidius, calore 30° liquescens."

The Pharmacopœia of Würtemburg puts the melting-point at 40°, the specific gravity at 0·89–0·91. The Belgian Pharmacopœia gives as the density 0·810.

Dorvault's 'Pharmacie Legale' gives the melting-point as at 242–5° C., and directs that ether be used for detecting adulterations, pure cacao butter being easily dissolved in 2 parts of ether at common temperature, the solution remaining clear, while when it is adulterated with tallow or wax, the solution becomes turbid.

Fehling's 'Handwörterbuch der Chemie' gives similar directions, and adds that if the solution gets turbid at 0° in less than ten minutes, the cocoa butter is adulterated; "the solution of pure cacao butter shows turbidity only after ten to fifteen minutes, such turbidity disappearing again at 19–20° C."

According to Hager, the pure cacao butter is soluble in 6 parts of anilin, and from the clear solution the pure cacao butter separates as a clear liquid layer; if the cacao butter contains tallow, then crystals and grains will separate.

Gmelin gives the specific gravity as 0·89–0·91, and the melting-point at 20–30° C.

Klenke in his 'Verfälschung der Nahrungsmittel,' puts the melting-point at 24–25° C., that of beef tallow at 30°, of mutton tallow at 35°, and of ox marrow at 37°, but considers the melting point as no sure criterion. He

* Read before the American Pharmaceutical Association.

says that drops of pure liquefied cacao butter dropped into warm water remain more or less globular, but if the cacao butter is adulterated with animal fat, the drops flatten, assuming a lenticular or discoid shape.

Muspratt gives the specific gravity as 0·90, but thinks it is not a test of purity.

The *American Journal of Pharmacy* (vol xxiii., p. 16) gives the melting point at 76° F., the congealing point at 60°F.

Mr. Henry W. Lincoln, of Boston, in a very interesting essay on this subject in the Proceedings of 1867, mentions also the test of dropping the cacao butter into warm water, and further says: "The best test, however, for any adulteration of cacao butter, is a cultivated taste, such as is only acquired by practice, similar to that employed by dealers in teas and wines, and can hardly be described. The point of fusibility is its first distinction. Bitten and placed on the tongue, its melts quickly and leaves no harsh taste, which it always does when adulterated with wax, spermaceti, tallow or stearin. Dropped on a warm iron it gives out its odour, and if adulterated largely, the peculiar odour of the article with which it is adulterated will be prominent. There is no doubt that it is sometimes largely adulterated, but although the writer has procured samples from various sources, he has not been able to find any that seems to be adulterated to any great extent, and he is confirmed in this by Dr. Hayes of Boston."

Dr. Squibb, in a discussion about suppositories during the convention of 1870, makes a rather sweeping statement in saying "all the cacao butter which is made is adulterated."

Hager and Jacobsen's 'Industrieblätter,' recommend the following method for the discovery of adulteration of butter: The butter is formed into candles, these are lighted, and then the light blown out, when an adulteration by tallow will be discovered by the smell. This a more troublesome, and as I found out by experiments, not more reliable test than the dropping on hot iron recommended by Mr. Lincoln.

This is now about all the information of any importance which I could gather as a guide to find out the best test for the purity of oleum theobromæ.

My experiments I began by preparing a quantity of pure cacao butter from Caracas beans by three different methods: expression, extraction by ether, and by bisulphide of carbon. The extraction by ether is less practical than by bisulphide of carbon, the former extracting with the fat a purple-coloured matter, while the later extracts the oil only.

To these three different portions of pure cacao butter I applied some of the above mentioned tests. In point of solubility in ether, and also in anilin, I found all three alike; not so, however, in their specific gravity and fusibility. The specific gravity of the first was found to be 0·850; of the second, 0·970; and of the third, 0·958. This great incongruity shows the unreliability of the specific gravity test. The melting point of two specimens I found 31–32° C., of the other 33–34° C.

Pure cacao butter dissolves easily within a few minutes at common temperature in 2 parts of ether, forming a clear solution, which sometimes separates after standing for awhile into two clear layers, the heavier layer (having the greatest bulk) being the larger one.

My experiments with butter of cacao and anilin (anilin from two different factories) gave a different result from that indicated by Hager. I found 1 part of butter of cacao soluble in 2 parts of anilin (not in 6 parts only), but the solution neither in the first-mentioned nor any other proportion ever separated into two layers. It is clear, but when concentrated somewhat thick, like very thin jelly. For the reason of this jelly-like appearance of the concentrated solution anilin is not quite so good a test for adulteration of butter of cacao with paraffin; the latter is a little soluble in anilin, the solution or mixture having a semitransparent gelatinous appearance. In ether paraffin is not soluble at a temperature below 0° C. At this temperature ether makes a perfectly clear solution, which at 35° C. congeals, and even diluted with 10 parts of ether forms a homogeneous, somewhat crystalline, and solid magma.

Having tested the pure ol. theobromæ, I made mixture in different proportions of it with several animal and vegetable fats, as beef and mutton tallow (freshly rendered and old), ox marrow with beeswax, Japan wax, Myrica wax, and spermaceti, and also with paraffin; then made solutions of them with different solvents, as ether, anilin, chloroform, bisulphide of carbon, oil of turpentine, and absolute alcohol, and subjected the mixtures and some of the solutions to the above-mentioned tests. As a result of this great number of experiments I found that none of these tests are infallible, but that several taken together would be a tolerably sure indication of the purity or adulteration of oleum theobromæ.

The best test I found to be ether. It indicated all admixtures which I had made to the cacao butter, with the exception of ox marrow, either directly by the turbidity of the solution of 1 part of the adulterated cacao butter in 2 parts of the ether (as is the case with the adulterations of tallow, bees-wax and bayberry-wax, and paraffin), or if not immediately after solution, then by becoming turbid after standing for some time, and by formation of little crystals and grains at the spontaneous evaporation of the solution, which crystals are not soluble again in 2 parts of ether at common temperature (this is the case with Japan wax and spermaceti with or without the addition of ox marrow). Anilin shows adulterations with tallow and wax almost as well as ether. The other above-mentioned solvents cannot be used as tests, all the different fats and wax being easily soluble in them, with the exception of bayberry-wax, which with chloroform only makes a clear solution.

Next to ether and anilin the taste seems to be the most reliable test. The dropping on hot iron or burning the mixtures with wicks, does not show plainly enough an adulteration with 25 per cent. of tallow, and of freshly rendered beef tallow even 50 per cent. could hardly be recognized. With Klenke's test I did not succeed; I was very seldom able to see any difference in the shape of the drops of cacao butter from that of tallow or ox marrow drops on water, the former expanding dish-like over the surface of the warm water about as much as the latter.

The specific gravity test is unreliable, as I have shown already. The same seems to be the case with the point of fusibility as a test; at least I found out that recently melted and recongealed cacao butter melts at a temperature several degrees lower than such as had been melted several weeks before. This may account for the conflicting statements about this point.

Guided by the result of the experiments made, I examined a dozen specimens of oleum theobromæ, which I had collected in different wholesale and retail stores. The result was as follows:

	Specific Gravity.	Melting-Point.	Taste.	Solution in Ether or Anilin.
No. 1,	0·850	31°C.	Pure.	Clear.
" 2,	0·897	33° C.	Pure.	Clear.
" 3,	0·900	31° C.	A little rancid.	Clear.
" 4,	0·874	30° C.	Pure.	Clear.
" 5,	0·976	34° C.	Not quite pure.	Turbid.
" 6,	0·938	32° C.	Pure.	Clear.
" 7,	0·979	34° C.	Very little rancid.	Clear.
" 8,	0·875	34° C.	Strongly rancid.	Very turbid.
" 9,	0·978	30° C.	Pure.	Clear.
" 10,	0·872	35° C.	Pure.	Very little turbid.
" 11,	0·919	33° C.	Pure.	Clear.
" 12,	0·959	30° C.	Rancid.	Clear.

This shows two or three adulterations among the dozen, one of them with tallow plainly recognizable.

In concluding, I must confess that the result of my labours is not quite satisfactory, because I did not succeed to find a sure test to distinguish ox marrow from cacao butter in the mixtures, but I shall continue my researches, and communicate the result, if any, at some later time.

MUSCARINE.*

BY O. SCHMIEDEBERG AND E. HARNACK.

Previous experiments upon the composition of muscarine gold chloride had indicated for it the empirical formula, $C_5H_{14}NO_2Cl + AuCl_3$, so that independently of the number of hydrogen atoms, muscarine appeared to be an isomer with betaine. Further investigation showed that free muscarine when heated yields a volatile base easily recognizable as trimethylamine. Muscarine was therefore assumed by the authors to be a trimethylammonium base, from which choline, or hydroxethylentrimethylammonium, differs, as it does from betaine, by containing an atom of oxygen less in the ethyl group. It had been supposed that upon the oxidation of choline by means of nitric acid betaine would be formed. Nevertheless as the identity of all the trimethylammonium bases isomeric with choline, but prepared in different ways, was not perfectly established, it was attempted by the authors first to obtain muscarine by oxidation of choline prepared from egg albumen. The experiments with potassium permanganate and chromic acid were negative, but by using concentrated nitric acid the conversion of this choline into muscarine was easily attained. It was believed, therefore, that the formation of betaine and muscarine takes place from isomeric choline bases. Experiment, however, gave no support to this assumption, for examination of the bases obtained from animal and vegetable sources, and described as choline, neurine, or sinkaline, showed that they were identical with one another, and with the synthetically prepared hydroxethylentrimethylammonium, and all yielded muscarine upon oxidation. The synthetic choline was obtained by the action of ethylenechlorhydrin upon aqueous trimethylamine at a temperature of 50° to 60°C. (Wurtz). The base was converted into the platinic salt and purified by recrystallization. The ethylenchlorhydrin was obtained by saturating ethylenglycol with hydrochloric acid gas, and heating in a closed tube to 100° (Wurtz). The glycol was obtained by boiling commercial ethylene bromide with an aqueous solution of potassium carbonate (Hüfner).

That the base contained in the fly fungus, and named aminitine, is also identical with choline, was apparent upon a comparison of the platinic compound. This occurs in large well formed klinorhombic tables, the sharp angles of which are mostly broken off, so that the crystals appear six-sided. The muscarine prepared from this choline was perfectly identical with that from the synthetic choline.

The identity of sinkaline with choline has been established by Claus and Keesé. The authors obtained the base from black mustard seed, and convinced themselves that its platinic salt had the same form as that of the synthetic choline, and that it could be converted into muscarine by oxidation.

The platinic salt of choline obtained from animal constituents presented several peculiarities, on account of the presence of impurities difficult to separate, so that it appeared to consist partially at least of a base differing from ethylene choline, but upon the removal of these impurities crystals were obtained identical with those of the synthetic choline.

In preparing choline from brain substance, a paste consisting of the brains of twenty-six oxen was boiled for two hours with a solution of barium hydrate, and from the evaporated filtrate an extract was prepared which was soluble in alcohol and in water; from an alcoholic solution the base was precipitated by platinic chloride. The precipitate, well washed with alcohol, did not dissolve completely in hot water, but left behind a brownish amorphous substance, of which a portion went into solution with a yellow colour when heated with much boiling water, but was deposited on cooling as a fine granular amorphous mass. Upon cooling the first aqueous solution, after concentration upon a water-bath, the platinic-compound of the brain base separated as a conglomerate of small slender irregular brownish-red crystals together with a quantity of a citron-yellow amorphous body, which could not altogether be removed by treatment with cold water or repeated recrystallizations. The choline platinochloride was therefore evaporated to dryness with excess of ammonium chloride and the residue extracted with absolute alcohol. The alcoholic solution, which contained choline chloride and was still slightly coloured, was evaporated, a portion of it was crystallized over sulphuric acid, the crystals spread on blotting paper, and placed without sulphuric acid under an air-tight glass bell until the blotting paper had absorbed all the mother liquor. The platinic compound prepared from choline chloride, thus purified, crystallized like the synthetic compound. The crude platinic compound prepared from the alcoholic extract of hens' eggs behaved similarly.

In the oxidation of choline to muscarine either the chloride or the platinic compound may be used, but the latter is the most suitable. The choline platinochloride is dried and powdered and concentrated nitric acid added; the mixture is then heated, at first gently until the solution of the platinic salt, and then the solution is evaporated, with careful stirring, rapidly to dryness. Excess of acid and non-nitrogenous decomposition products are removed from the mass after cooling by washing with alcohol, and the residue is treated with cold water which dissolves any unaltered choline platinochloride, and leaves the difficultly soluble muscarine compound. As the greater part of the choline escapes oxidation the filtrate may be evaporated and a fresh quantity of muscarine platinochloride obtained by submitting the residue to oxidation. It is preferable to repeat this operation several times rather than carry a single operation too far, but there is always a great loss of choline through the formation of by-products, especially if the action of nitrous acid be not avoided. The oxidation should always be carried on in the presence of the least possible quantity of water. With dilute nitric acid numerous by-products are formed, but sometimes no muscarine.

Betaine as a product of the oxidation of choline was not observed by the authors during their experiments, but no special search was made for it. The muscarine platinochloride obtained in this way was purified by recrystallization from hot water. It separated from the concentrated solution upon cooling in more or less well-formed octahedra, which seldom exceeded a pin's head in size, and were sometimes aggregated together. The compound had the composition $(C_5H_{14}NO_2Cl)_2 + Pl\,Cl_4 + 2H_2O$. Upon drying it did not give up its water of crystallization readily, the second molecule being lost only just previous to decomposition, which took place at 150° to 155° C.

Muscarine chloride can be obtained by evaporating an aqueous solution of the platinic compound with an excess of potassium chloride to dryness, and extracting with absolute alcohol which dissolves the muscarine. An excess of potassium chloride is necessary for the complete decomposition of the muscarine platinochloride. The potassium chloride may be still more perfectly removed by again evaporating this solution to dryness, treating the residue with absolute alcohol, adding to the alcoholic solution one-fourth its volume of chloroform and after a time filtering. From this solution, when concentrated, the muscarine chloride is deposited upon standing under an air-tight bell glass, frequently in large, colourless, shining, not quite regularly defined crystals, but principally in variously grouped needles or well-formed pointed prisms, which do not effloresce over sulphuric acid, and deliquesce rather readily in the air.

The muscarine hydroxide is obtained by treatment of the choride with moist silver oxide. It forms upon evaporation of the aqueous solution *in vacuo* a strongly alkaline readily deliquescent mass, which solidifies in a crystalline form in the exsiccator.

* Abstract from a paper in the *Archiv für Experimentelle Pathologie u. Pharmakologie*, vol. vi., p. 101.

The Pharmaceutical Journal.

SATURDAY, MARCH 24, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE BOTANICAL PRIZE.

It has frequently been the subject of regret that the silver medal given annually by the Pharmaceutical Society for the best Herbarium collected under certain conditions does not evoke a greater amount of competition. We have therefore received with great interest the correspondence respecting it which was initiated by Mr. F. J. HANBURY, and consider it worthy of most careful perusal to see whether any of the suggestions put forward are calculated to remove any existing obstacles to a more general competition.

There are two points to be kept clearly in view in the consideration of the question: (1), the object specially sought to be attained by the foundation of the prize; and (2), the conditions which, while keeping this object strictly in view, will influence the greatest number of persons to compete and enable them do so upon the most equal terms.

The object, as fairly quoted by a correspondent this week from a quasi-official statement published about the time of the institution of the prize in 1856, was undoubtedly to infuse into the minds of the coming generation of pharmacists "a due appreciation and a "practical knowledge of the structure, characters, "classification and properties of plants, *especially* "*those which are comprised in the Materia Medica.*" The herbarium was adopted as a means to this end, because it was thought that in its collection the pharmaceutical student would be compelled to acquire an acquaintance with the rudiments of botany that would greatly facilitate his study of the plants more especially belonging to his department. This, therefore, does not seem to demand so much that the specimens should be rare, or even numerous, as that evidence should be given that they have been carefully studied and not merely collected.

A primary essential is that, so far as possible, the results should be measured by one standard. Consequently, Mr. HANBURY's recommendation that the nomenclature, sequence and numbering of one authority, such as the London Catalogue, should be followed, instead of leaving a choice, is an important one. Of course, it does not necessarily follow, because the collector following BENTHAM could only collect one *Rubus*, whilst another following HOOKER might collect forty, that the adjudicator would place the latter at an advantage of forty to one in his award, although the official statement that in estimating the merits of the collection not only the number of species but their rarity will be taken into account might be considered to imply as much. But there would be an advantage even in the avoidance of any ambiguity or cause of perplexity. Mr. HANBURY's suggestion that the student should be allowed to use herbaria as well as books to aid him in the naming of his specimens is also a good one, although we are inclined to think that this clause has not been so strictly interpreted according to the letter in the past as Mr. HANBURY would appear to think.

The limit of the age of competitors is another point worthy careful consideration. It is perhaps true that between the age of twenty-one and twenty-four a man might study botany with facilities he had never before possessed, but this only heightens the contrast when these conditions are compared with those of an apprentice still serving his time. We are decidedly of opinion that if the limit of age be extended, it will become necessary to divide the competitors into two classes, or else, so far as the prize is concerned, the younger students will give up the contest in sheer despair.

Another most important question arises as to how far mere number or rarity of the specimens should affect the competitor's position with respect to the prize. We confess that the words in the regulations, already quoted, give some colouring to our correspondent's assertion that the man who lives in the richest botanical district, and has the most time to spare and the deepest pocket, will infallibly carry off the prize from a less fortunate and poorer competitor. We are almost sorry to note that it is now tacitly assumed that a herbarium to have a chance of success must contain five or six hundred plants. Seeing that the bulk of the working time for collection must be concentrated within six or eight months, a simple calculation will show how utterly futile it would be for many of our younger friends, for whose special benefit the prize is supposed to exist, to expect to find the spare time, or even the spare money, necessary for gathering so great a number. It is worthy of consideration how far Professor BENTLEY's suggestion might be utilized to meet this difficulty, in the marking out of botanical districts to one of which each collector should be limited. But at least equal in value is the suggestion made this week by "A Former Competitor," that the illustration of species by dissections and descriptions of the distinctive characters and properties should have their value in the estimation for the final award. There would also be this further advantage that some of the work could then be done during the winter months.

As the time has so nearly arrived when the usual annual announcement concerning the botanical prize will have to be made for next year, it may not be practicable to make any alterations in the regulations at present. But nevertheless in calling attention to the subject, and expressing his views upon it, we consider Mr. Hanbury has done useful service.

JAPANESE HYDROPATHY.

One of the most remarkable national transformations of modern times has doubtless been that which has resulted from the introduction of the civilization of the West into Japan, and prompted her sons to compete for wranglerships at Cambridge. Already there has been created in Yeddo a Faculty of Medicine, where the science is taught to native pupils according to European notions by professors drawn from Germany, and more recently help has been requested from France to assist in the establishment of a Faculty of Law, and the organization of a system of superior education in the capital of Japan. In aid of this movement MM. Mangeot and Berson have been charged with a scientific mission by the French Government, at whose request the Academy of Medicine has presented a scheme drawn up by M. Jules Lefort, to assist them in the systematic investigation of the geology, mineralogy, volcanoes and mineral waters of the country. From this report we borrow a few details.

The mineral and thermal springs of Japan are known to be very numerous and many of them of a high temperature; in fact, it is asserted that only Japanese who are accustomed to very hot water from their infancy are able to bathe in some of them, and it is probable that their virtues are occasionally entirely due to their elevated temperature. But most of the springs may be included in one of two classes, the sulphurous and the chlorinated, the ferruginous waters being very few. One of the most frequented, that of Kourats, about fifty leagues from Yeddo, was found upon analysis to contain per litre 1·34 gram of free sulphuric acid, 2·20 grams of sulphates (mostly aluminum), 0·85 gram of free hydrochloric acid, and an abundance of sulphydric acid.

The methods of using the waters appear to be very primitive. For applying the *douche* the water is conducted in troughs to a point from which it has a fall of several metres upon the bather, who receives it upon the part of his body affected, the duration of the operation being limited only by the patience of the patient. When the water is too hot for this method, and in one case it reaches 91° C., instead of lowering the temperature, as in Europe, by the addition of fresh water or exposure to the air, a number of attendants beat the water with flat boards, scattering about a plentiful spray and disengaging volumes of sulphurous vapour which envelop the bathers in a semi-transparent cloud.

The bath, therefore, in this case partakes pretty closely of the nature of a vapour bath, and it is evident that the portion of water which reaches the bathers may differ very considerably in its constituents from the bulk as it issues from the spring.

YORKSHIRE COLLEGE OF SCIENCE, LEEDS.

The Council have just arranged for the purchase of the Beech Grove Hall Estate, comprising about 3½ acres, and situated a mile from the more central of the railway stations, and within sight of the Grammar School. The sum to be paid to the vendor is £13,000. It has also been decided to add to the curriculum Chairs of English Literature and Classics, experience showing that many candidates for science degrees require instruction in these subjects.

The amount promised to the college is now about £43,000, besides the endowments received from the Company of Clothworkers and the trustees of the Akroyd Charity.

THE CHEMICAL SOCIETY'S DINNER.

On Tuesday last the President, Fellows and Friends of the Chemical Society dined together at Willis's Rooms. About 200 sat down to dinner. The toast of "Armed Science and its Representatives" was responded to by the Inspector-General of Fortifications, the Director of Artillery, and the Assistant-Director of Naval Ordnance; that of "The Learned Societies," by Professor Huxley and Mr. Bramwell, C.E. "Success to the Chemical Society" was proposed by Professor Odling. We are informed that the Worshipful Company of Clothworkers and the Worshipful Company of Merchant Taylors have each contributed one hundred guineas towards the Society's Research Fund.

We regret to learn of the destruction by fire, on the 16th inst., of Cumbernauld House, which had been recently leased to Mr. Daniel Frazer, of Glasgow, and was at the time in the hands of the workmen preparatory to his taking possession. The house was an old baronial mansion, built in 1731 by John, sixth Earl of Wigtown. It is curious to note that on another page Mr. Frazer is recorded as having recently lectured on Fire as one of Man's Servants.

Mr. A. P. Luff, Pharmaceutical Chemist, and formerly a "Bell Scholar" in the School of Pharmacy Bloomsbury Square, has been appointed Demonstrator of Chemistry in St. Mary's Hospital, Paddington.

An application made by a lady, who had kept a homœopathic pharmacy fifteen years, for registration as a chemist and druggist under the section of the Ontario Pharmacy Act, which saves the rights of persons engaged in business prior to the date of its passing, has been refused on the ground that the law does not apply to dealers in homœopathic medicines.

As will be seen by the advertisement on another page, the Calendar of the Pharmaceutical Society is now ready, and may be had upon application to the Secretary

Transactions of the Pharmaceutical Society.

NORTH BRITISH BRANCH.

The sixth meeting of the present session was held in the Society's Rooms, 119A, George Street, Edinburgh, on the evening of Wednesday, March 14, Mr. Wm. Gilmour, President of the Branch, in the chair, when the following paper was read—

BOTANY, IN REFERENCE TO SOME MODERN SPECULATIONS.

BY HENRY B. BAILDON, B.A.

Mr. President and Gentlemen,—My paper, to-night, is in some sort a continuation of the previous one on chemistry, although neither mutually nor individually are they so logically arranged as I could wish. Before commencing, I would like to guard against misapprehension on the part of those who are now present, or who may read any report that may appear of what is said. In the first place, if I have occasion to refer to great and well-known scientific names, and, it may be, to endeavour to show their conclusions to be erroneous, let it not be thought that I would for one moment compare myself with them in point of knowledge of facts, but rather that I think myself, or any sane person, quite competent to combat their conclusions from mutually admitted facts. In the second, I do not wish it to be thought, that my arguments are intended to support any special religious view or scheme. That our view of nature must affect our religious belief there is no doubt, but to press conclusions home into the region of religious conviction would be here extremely out of place.

In resuming our subject I would ask you first to look broadly and generally on the contents of the universe, and mark the two great divisions into which the whole may be divided. They may be denominated Force and Matter. But let us at once guard against the crude error of supposing that because these two between them embrace all phenomena, that either of them is necessarily homogeneous, so to speak, that is, that either all force or all matter is the same in kind. They are mere generalizations, and are incapable of definition or conception apart from each other. Force is that which moves, changes, constructs, organizes, animates matter, while matter is that which is moved, changed, constructed, organized by force. Force acts, matter is acted on. Force is the active, matter the passive. Let us bear in mind that at this point we have attained to no knowledge regarding either force or matter, but have simply agreed to use these two words as equivalent to the active and the passive states of being in the universe. It is just like the beginning of a sum in algebra, when we write down—Let $x =$ so and so and $y =$ some other thing, both unknown for the time, and only ascertained at the conclusion of the problem. We cannot go further back and define either force or matter more simply. It cannot be said that matter is that which is perceptible by our senses, for apart from force it is not perceptible. So at the outset we must content ourselves with agreeing to make force stand for all the active, and matter for all the passive. There are a series of relations between force and matter, which by the nature of things and the constitution of our minds we are compelled to regard as distinct.

The lowest and most universal we must style mechanical or dynamic though the phrase is not specially happy. All matter is subject to, and is even to be regarded as constantly under the influence of this mode of force. Newton's announcement of universal gravitation referred to this moving or mechanical force, as existing between every particle of matter and every other, and drawing them together by a force inversely proportional to the square of their distance. Molecular force may also be classed as mechanical, and indeed, as I suggested before, may be absolutely identical with gravitation. The definition of this force authoritatively given is "That which produces or tends to produce motion. Under the spell of this force every particle of matter animate or inanimate lies. But it will be clear to you that such a definition does not apply except in an indirect or metaphorical manner to all force, so although this force is a universal it is not the only force. Indeed the next mode of force we come to consider is also universal, though not constant in the sense that gravitation is; it is known as chemical. Now, if we may regard gravitation as the *constant* force possessed by each particle in common with every other by virtue of its being in some respects *identical* in quality with all these, chemical affinity must be regarded as a *varying* force possessed by each kind of matter by virtue of its *differing* from other kinds. No chemical affinity exists between substances chemically identical. Instead of like drawing to like it is unlike to unlike. This, I think, is as near as we can get to a definition of chemistry or chemic force. The one may be called the study of the differences of matter, the other that force which binds the different kinds of matter together. Hence chemical affinity is a very distinct phase of force to the mechanical or motor, represented by gravitation. Before proceeding to the higher modes of force, it will be well to note a mode which seems to take rank between the chemical and the organizing, and still to bear a relationship to the mechanical; it is the constructive or crystallic, which arranges matter into definite forms, and is for inanimate matter what the organic is for vitalized. It represents nature's primal effort at definite and beautiful form. But on this point we must not linger, seeing we are not yet over the threshold of our proper subject.

Those forces or modes of force which we have already noted are those which influence all matter, whether animate or inanimate, dead or living, but that which now comes to be treated of is peculiar to living or vitalized matter. And here it must be admitted lies no small difficulty, for in living organisms both mechanical and chemical forces are constantly at work, so that it becomes frequently a very perplexing point to decide as to whether certain phenomena are due solely to chemical or mechanical agency, or are to be attributed to a special vital force. While the attempt is constantly being made to explain all vital phenomena on purely mechanical and chemical grounds, it may safely be said that such attempts, however far they may have seemed to succeed, have never attained anything like complete and permanent success. I will, therefore, make bold to assert that neither chemical nor mechanical force, nor the two combined, ever yet produced an organism. It will, therefore, be the most distinctive title to confer on this phase of force peculiar to living matter if we call it organic, meaning by that term the force which forms and maintains organisms. It is usual to divide these organisms into two classes, vegetable and animal, although there is no doubt that primitive organisms are so slightly differentiated that it is a delicate task to assign some of them their respective class. This evening we shall confine ourselves to the consideration of vegetable organisms.

In vegetable life the simplest organism is the *cell*, which is to botany what the atom and the particle are in chemical and mechanical science. A plant may be said to consist of one or more cells; when matter is organized into a living cell that cell is a plant (or animal). There is sometimes a distinction made between cells and vessels; but it seems to me an arbitrary and dangerous one, for it is quite impossible to mark the point where the one passes into the other, and the best authorities seem to agree in regarding the so-called vessels as modified cells. It is, therefore, perfectly correct to say that a plant consists of one or more cells. The characteristic of cell is that it has an inside and an outside, an envelope, and something enveloped, unlike the particle and the atom, which are conceived of as solid and homogeneous. Let us consider, then, this cell as it exists in its simplest and most primitive form, a new-born being amid dead deserts of matter, a plant complete in all its functions, and yet but a tiny bag of matter without a single defined organ. We would fain surprise this marvellous entity at the moment of its making; catch, as it were, the maker or makers tool in hand. We are anxious to know the receipt for this genuine elixir of life, and we shall be, I suspect, like the alchemists of old, for ever on the verge of its discovery. Scientific men are not even agreed as to whether this organism can arise spontaneously, as it is called, or whether germs must be present before the plant can be produced. Whichever way it be, the wonder, the miracle is the same. Nature seems smilingly to confront us like a confident and accomplished *prestidigitateur*, when he says to the audience, in regard to a trick he has just performed, "Oh, it's quite simple! That's how it's done!" and no one is a bit the wiser. So nature's miracles are worked before our eyes, and she seems to say "Oh, I've no secrets, no concealments, I assure you! That's how it's done!" and we gaze at the proceeding up a telescope or down a microscope, and rub our eyes exactly as wise as ever. Yes, this simple cell marks an era in creation; it is the tiny ancestor of all plant-life. That from so simple and apparently insignificant a beginning, the whole of the plant system, from the lowliest lichen that grains the bared boulder with silver, emerald, crimson and ebon to the stateliest mountain pine and the delicate sweet-breathed primrose of the wood, should have been slowly evolved throughout the patient centuries ere eye of man beheld them, seems an idea so stupendous as to be almost incredible. Yet it is an idea not degrading nor humiliating, not irreverent nor revolting, but sublime, and solemn, and beautiful. Its contemplation bows the spirit down with a sense of infinitude, akin to that we experience as we gaze upward on the countless companies of stars, and strive to realize somewhat their magnitude and distance, till the mind falls back abashed from the enterprise. Equally impossible is it for us to trace in imagination those gradual and imperceptible mutations, those insidious invisible changes by which this astounding evolution has been accomplished. In all this there is for the mind, though at first inclined to start aside from the apparent incredibility of the notion, a fascination almost irresistible. For this conception of the history and origin of vegetation appeals to two of the strongest and seemingly antagonistic mental instincts of man, the delight in the marvellous and the passion for simplicity.

From what I have just said it might be expected that I should declare myself an euthusiastic Darwinite. But I am not. I have read a great part of Mr. Darwin's 'Origin of Species,' and although he certainly does remove many apparent objections, brings forward much that tends to show that great modifications have taken place in structure and that the difference between species and variety is chiefly in degree, and has gallantly assailed several very formidable difficulties in the way of accepting his theories, still on the whole there is very little that is conclusive or quite satisfactory in the work. But this should not occasion surprise nor should it be considered derogatory to Mr. Darwin's merits as an investigator, seeing how vast is the field he has undertaken to explore and how extremely fragmentary and imperfect is the record we at present possess of the past history of our globe. He is continually compelled to pull up short with the admission that too little is known to warrant conclusions. But there is about his writing a conspicuous candour in admitting the magnitude of the difficulties his theory encounters, while, at the same time, he vigorously defends his position. The main points in his favour are these:—the extensive modifications producible on plants and animals under domestication with artificial selection; some remarkable cases of reversion in various breeds to certain characteristics of a common ancestor; the close anatomical similarity in particular points observable in creatures of extreme diversity; the existence of rudimentary organs; and last, but not least, the absence of any definite opposition theory on an adequate scientific basis. The weakness in Darwin's Darwinism seems to me to lie in the insufficiency of his great factors, the struggle for existence or survival of the fittest and sexual selections to account for all forms of life. I will not attempt at present to go into details, but must be content to observe generally that the survival of the fittest is a most objectionably elastic phrase, which sometimes comes to mean merely the survival of the survivors, and, as regards sexual selection, to which Mr. Darwin attributes so much, while he has shown the operation of the principle he has forgotten to account for the origin of the instinct for the beautiful thus assumed as existing in animals. If the above statements as to the present condition of the controversy are correct, it follows that while a strong case may be made out for evolution as a fact, the Darwinian modes of accounting for this fact have not as yet proved themselves efficient.

Assuming the foregoing to be valid, I would proceed to strengthen the case for evolution (considered as a fact) by pointing out the notable analogy between life generally considered as an evolute, and the origin and history of the individual life. If it is thought incredible that in the course of long ages the various forms of life should have been developed from a small and simple origin, is it not equally incredible that a highly organized plant or animal can be evolved from a minute spermatazoon or seed in the space of a few weeks or months? Yet we contemplate the wonderful birth evolution daily without surprise, because it has become so familiar and is, indeed, so universal. Nor does the use of the term evolution in regard to the genesis of the individual lack some confirmation from clear fact, for the embryo does in a manner seem to pass through evolutionary stages, and the embryos of widely different species, even belonging to different classes, are at some stages indistinguishable. Evolution is, indeed, but the generalization or fulfilment of the dictum, *Natura non habet saltum*, wherein lies the alpha and omega of physical science. Whoever admits this maxim to be universally true is not only entitled but committed to a belief in evolution, whatever cause or causes he may have to assign for the phenomenon. If there have been no leaps or breaks in nature, either in the present or the past, creation has been an evolutionary, gradual process, as all growth is, and not a series of creative efforts after which the creatures produced were, so to speak, left to take their chance. It is extremely unfortunate that the term creation should have become so narrowed in meaning as to be applied only to a sudden instantaneous calling into being of what before had no sort of existence. From this it arose, that Mr. Darwin, while able as a man of science, was too little of a philosopher to avoid the use of this word in this very sense. Thus, in his anxiety to avow his deism, he banishes the action of his Deity to a remote period of the past, leaving him as it were at the very verge of his own universe, in such a position, too, that he must recede continually before the advance of science. That Mr. Darwin by no means intended to leave the deistic idea in this perilous position may well be believed; it was his ill-timed zeal in giving his bow of belief at the end of a volume which he could not but be aware was of an atheistic flavour, that did most of the mischief. His followers have seen the weakness of his position, and have many of them gone on to atheism. Now I trust I shall not be misunderstood, but that you will bear with me till I have fully explained myself, when I say that science must always be in a sense atheistic. By atheistic here is meant not what denies deity but what leaves it out of account. Science, so far as it seeks to pierce to causes and not merely record and classify facts, seeks only the particular, finite, intelligible or secondary cause, and has no concern with the universal, infinite, or first cause. When, for example, we say to a child that God made such and such a thing, we give the child no scientific information whatsoever, though we impart a religious truth. If, however, we proceed to give a scientific account of its origin, we find ourselves unable to exhibit the deity as acting in the matter, except at the point where our knowledge of particular causes ceases, when we are reduced to a simple acknowledgment of ignorance or reference again to the deity as an immediate agent. Here there is apparent the necessary and inevitable antithesis between the religious or theologic and the scientific aspect of nature. Now this fact that of necessity science must look at things from the atheistic standpoint deprives its apparently atheistic drift of all final significance as militating against a belief in the deity. For it only arrives at the point from which it started. Having assumed the causes of phenomena to be finite, intelligible, natural, it comes back with the same belief; for time and space, the great magicians, work the miracle of breaking up the infinite into an infinity of finites, each intelligible in detail. Still the true province of science is not the discovery of the ultimate reason or cause of phenomena; its true function is to observe, discover, register, classify, and accurately denominate and particularize phenomena; the other is the function of philosophy. And the simplest way of discriminating the aims of these two is to say, philosophy seeks an answer to the question, Why, by what cause and for what reason is a thing so? Science asks merely, How, in what manner, by what stages does a thing become so? Philosophy seeks to comprehend, science merely to know. Science must thus invariably form the material to which philosophy seeks to give shape, or the substratum or foundation over which philosophy builds. We are rather apt to imagine science to be a modern growth, whereas in fact it begins with the beginning of man, being at first small in the number of facts known and almost devoid of classification. But the veriest savage knows a certain number of facts and has probably discriminated them into classes in his mind, and this is as much science in *kind* as the works of a Faraday. This, no doubt, is putting an extreme case; but when we are told that Solomon knew every plant, from the cedar to the hyssop, it is clear that he is entitled to be called a scientific man (however little we may know of his system of classification) just as much as a Darwin or a Huxley. Upon his science, then, whether it be the few and ill-assorted facts of the savage, the extensive acquirements of a Solomon, or the great and carefully classified information of a modern scientist, does a man found his rationale of things, in short his philosophy. The distinction thus indicated is highly important in this regard that, as the functions of science and philosophy differ, so also do the mental faculties which they call into play and require for their prosecution. Hence a man may distinguish himself in science and yet prove a mere tyro and blunderer in philosophy, while another ill-adapted for laborious observation, calculation and experiment may wield the results of science in a masterly manner to philosophic ends. The requisite faculties and tastes for both might be combined, it is true, but we must bear in mind that the probabilities are greatly against such a combination and therefore should be chary of accepting the attempted philosophy of a scientific man, as though it were necessarily of authoritative weight. In the converse case the warning is not so necessary, perhaps, as a philosophic writer usually prefers reference to acknowledged scientific authority to original investigation. By all means let science become as powerful and perfect as she can, but let her not be suffered to lay on our souls the yoke of a coarse and mechanical philosophy.

Before we leave the consideration of the evolutionary hypothesis as a general scheme, I would like to state as clearly as I can what my own conception with regard to the creation or origin of the physical universe is, in order that you may perceive the drift of my remarks. Of course it is merely an individual opinion or belief, the result of the interaction of my individual mind and the facts which have been laid before it. It is best expressed by saying that I conceive the becoming of physical phenomena to have been evolutionary as to mode, but miraculous or divine as to cause. To illustrate more definitely I would say, that if a human being had awoke to intelligence and consciousness at any period of the creative process, howsoever remote, and had been a perpetual witness of it up to the present time, it would have presented to that mind a series of gradual changes and imperceptible mutations as apparently natural as the aspect of nature we now ourselves perceive; but, at the same time, that the process thus perceived was not automatic, still less accidental or tentative, not the result of a fortuitous concourse of atoms but the work of the supreme and external power of whom it has been sublimely said, that with Him, "One day is as a thousand years, and a thousand years as one day" Such a creed appears to me to include and sublate in itself the theologic and the scientific creeds, and in this position the mind may abide without any fear that new facts or novel theories can imperil its security or invade its peace.

Let us now revert from these generalities to consider more in detail the phenonomena of vegetable vitality, the manifestations of vital force. In doing so, we naturally commence with the lower phases of plant-life. Now there is a certain modern school of philosophy, if it be worthy of that august title, which is so eager to exercise a destructive dialectic and disintegrate thought into an irrational chaos, that its exponents might cavil at the use of such terms as lower and higher, and demand at the outset a justification of their employment. Let it be remembered, then, that we are men, and as such, either really the highest visible phase of being on the earth or, at the lowest, are compelled by some inherent conceit to think ourselves such. The main characteristics of man are that he lives, moves, thinks, feels, wills. Inanimate matter is incapable of any of these actions and thus stands as the antithesis to man at the bottom of the scale of being. Between the two extremes there are a series of delicate gradations. That, then, which is further from man by defect of these powers and nearer to mere matter, we are justified in calling lower than that which approaches man in these faculties. If we add that in man the functions are more specialized, we shall be in a position to arrange creation in its true order. There are no doubt many cases in which it might seem difficult to balance claims. It might be pleaded that an oak is higher than an earthworm or some low parasitic form of animal life. But we are, nevertheless, justified in saying that an animal is higher than a plant, because an animal can be produced possessing faculties more nearly approaching the human, than any plant does. It is perfectly legitimate, then, to class all flowerless plants, *i.e.*, those which do not specialize their reproductive organs, as lower than flowering plants, and also to assign to what are called cellular plants a lowlier position than those exhibiting a varied tissue.

There is no objection, then, to our calling, as all scientific men do, the Algæ, Lichenes, and Fungi the lowest orders of plants. It is remarkable, with regard to the two former, on what a slender and hard fare they seem able to exist. Well fitted do they seem to be the first hardy colonists of a naked planet, while as yet there was no true soil formed, and the one had to bivouac on the rude boulder and cliff, and the other fastened upon the submerged rock, the first missionaries of life to a sterile land and a barren ocean. The one to weave with lithe green arms the wondrous labyrinth of submarine vegetation, the haunt of forms of strange beauty and horror, as though they were not meant for the gaze of man; the other working humbly and, it would seem unselfishly, by insensible accumulations preparing the place for another till it dies the victim of its own industry, and yields to a workman the modest moss, more active but hardly any prouder, building itself up by its own decay, and yielding with no less pathetic self-surrender. Beautiful is it to observe these two still at their silent labours, covering with secret assiduity the nudities of nature, or borne on the great trunk or limbs of a forest tree whose life their bygone generations had laboured to make possible. To the fungi seems to belong, in the main, the less noble function of promoting and flourishing by the decay of organisms higher than themselves. Some indeed appear of purer instinct and sweeter feeding, as the creamy skinned mushroom with its dainty flesh-pink gills; but for the most part the fungus is a minister of decay and corruption. On the dank and moribund tree-stump its blackened, rot-bringing ridges extend; it squats in dark hollow of the fated trunk, curling its cancerous lip, as though it were some imp of corruption leering in malign pleasure over its anticipated triumph,—at once the slow assassin and the sexton of its nobler fellows. Still it is as much the servant of nature as others of gentler office. So long as an organism can retain its vital activity, and thus keep on duty, as it were, the matter it has absorbed into itself, nature seems to lend willingly enough. But as soon as the vitality flags, nature with stern economy demands back the loan, and despatches her certain ministers of decay to restore it again to her bosom. From this view of the diverse functions of these classes of plants, it will be amply evident that either the Algæ or the Lichenes must be the primal order of vegetable organisms, because there must first be life, before there can arise that mode of life which subsists by decay. One might expatiate long on the variety and beauty of these humble ranks of plant-life. It would be difficult to over-estimate the precious effect of the Lichenes alone in adding to the delight we reap from the appearance of natural objects. Even in looking at a wide landscape we must always owe somewhat to these lowly artists. On the boles and even the branches of the trees, and on ruin, cottage, fence, wall, and boulder, they have been at work, and with their silvery whites and greys, cool greens and bold blackness, must have greatly assisted in producing those subtle harmonies of tone and colour which delight our æsthetic sense. By this agency it is that the artificial structures of man are reconquered into the realm of nature. And if we look more closely every stone appears a study of colour and of blending arabesque outlines. To the Algæ also, apart from the strange splendours of submarine vegetation, we owe much of beauty that is visible from the land. To their presence, I apprehend, is partly due that play of shoaling colours, mainly green and purple, near the shore, which is one of the most brilliant and gorgeous aspects of the sea. Such are a few mere random hints on an extensive subject.

It is both according to the natural and the acknowledged order, if we now proceed to consider the Filices, Equisetaceæ, Musci, and Lycopodia, the Ferns, Horsetails, Mosses, and Lycopods. Here first of all we find the plant aspiring to rear itself above the earth, and it is significant that, in order to do this, it also descends into the earth. The stem and the root appear simultaneously, and seem to involve and imply each other. Hitherto the functions of nutrition and assimilation have been carried on by the general surface of the plant, now a certain portion is directed downwards in search of nutriment of one kind, and one directed upward to reach influences and support of another kind. The former we call the root, the latter the stem. The plant in this stage is more individual, more distinctly a vegetable ego or self than in the lower forms, and asserts more clearly its vital properties. The root exhibits faculties separated from anything merely mechanical or chemical by an impassible gulf, faculties such as its selective power, which is thus described by De Saussure:—"Each plant can take up from the soil a different amount of each substance contained in it, even though these substances should be all in the same proportion in the soil originally; in other words roots have a selective power, and only take up what is necessary to life, and that too, in the proper proportions." And the proposition that this power is super-mechanical, may be maintained even in the face of such ingenious suggestions as that of the same author who contends that the preference of a plant for one substance before another in the same liquid, is due to the different degrees of fluidity or viscosity of the different substances; so that the roots of plants are filters of the most perfect and delicate description possible. This will not do; for it is surely incorrect to conceive a liquid containing different salts in solution as consisting of solutions of differing degrees of fluidity and viscosity. This viscosity depends on the aggregate of the dissolved substances, and is constant throughout the liquid when solution is perfect. Besides, if this theory were the true one, the proportion of the substances taken up would vary inversely with the amount in solution, which it does not do. Filters in a sense the rootlets are no doubt, because, like filters, they allow no solid matter to pass through them. But solid matter is not concerned in the question, since it is never taken in by any plant at all. Unpalatable, then, as it may be to the scientific mind, it seems to be an inevitable conclusion, that this discriminative faculty is more nearly allied to a sense or instinct than to a purely mechanical arrangement. Nor need the fact that a plant will absorb energetic poisons invalidate this conclusion, seeing that, apart from the probability that the poison first destroys the sensibility of the surface before it is absorbed, it is a strong characteristic of what we term instinct that it is not equal to unusual emergencies, but invariably fails before them. Vegetable instinct, also, is doubtless very dim and dull in comparison with that of the higher animals, who, it must be remembered, possess also thought, but it is also wonderfully adequate to its own ends. It is surely much more scientific to describe such properties as this, and that of storing up in summer supplies for autumn use, as vegetable instincts, than to attempt to reduce them to mechanical contrivances. With regard to this economic and provident instinct, which roots display, the exponent of the survival of the fittest would doubtless argue that those which stored up had an advantage over their competing fellows and so the practice was increased and perpetuated. This will not, however, account for the fact, for, if we suppose, as the Darwinian would, that some of this supply was stored up by a chance in one root first of all, it would be of no use to it, unless there arose simultaneously the faculty for using this supply, the power of performing the necessary transmutations, and this power cannot be supposed to have been pre-existent to the necessity for it, and could hardly have sprung into existence by a mere varietal freak, just when wanted. In such attempts as the above example to reduce the progress from lower to higher forms to an automatic and necessary process, and which is the stock form of argument with the Darwinian school, the aim seems to be to get rid of the notion of contrivance and design and replace them by the notion of adaptation. That this vital elasticity or power of self-adaptation exists there can be no reasonable doubt; we see it in the hardening of the mechanic's hand and in a hundred every-day circumstances. What the Darwinist with his lack of metaphysical acumen fails to see is, that this very adaptability is itself the most perfect of contrivances and the deepest of designs. And this elasticity, this principle of yielding within certain limits, is a universal one. Nothing is absolutely rigid. The stone or piece of hard metal yields to the pressure of a finger enough to be ocularly demonstrable under the microscope. The mechanical elasticity of dead matter consists in the power of both yielding and resuming its form when pressure is removed. Vital elasticity or the adaptive power of organisms consists in the faculty of recovering from a temporary disadvantage by a change which meets the fresh exigency and even turns it to advantage. This is obviously distinct from and an advance upon the other. But here we are getting too far afield into the general question and must return to the special point under consideration, which was the selective sense exhibited by the roots of plants. In addition to this sense, as it may best be called, the roots of plants show also an instinct for method and symmetry. In proof of this I will quote the summary of Clos's discoveries on this subject, given in Brown's 'Manual of Botany:—

"The regular arrangement of the radicles is chiefly observed in the young plant, and gets less and less apparent as the plant increases in age. All the radicles in every root are produced one above the other, so that they appear in the form of longitudinal lines. However, in certain cases the lines follow an oblique and not a rigorously vertical course. This Clos calls 'The Law of Superposition.' The number of these longitudinal rows is fixed and determined either for the plants of the same order or for those of the same genus, or at least for the individuals of the same species. The rows are separated from each other by equal spaces: in number, according to the vigour of the plant, from two to five, the latter number being rare."

By such facts as these the supposition of some dull-witted scientist that the radicles come through just where the epidermis happens to be thinnest, at the points of least resistance as he phrased it, is shown in its naked and native absurdity. No doubt the radicles come through at points they have power to come through, but that is surely no discovery. It is also certain that the root, in contest with an obstructive soil, gets warped from its symmetric ideal, so to speak. Nevertheless, I believe, though of course it would be a point very difficult to establish, that even in adult roots there exists a subtle and complex symmetry on which the eye reposes with pleasure, though the mind cannot completely analyse the concurrent sources of the effect. Whether it arise from this original arrangement of the rootlets from their truly graduated tapering, their wayward, yet balanced, division, their suave or sharp flexures; from a conspiracy of all these or from the suggestion of a delicate and discerning energy, this to me is a matter of experience that an accurately drawn engraving of a root yields generally a pleasant sensation to the eye. Here, then, we discover in a plant-root, delving arduously for nourishment in a resisting soil, a dim aim at and instinct for beauty, which, how unconscious soever it be, links it with the loftiest achievements of the sculptor and the architect, exhibiting, as it were, the signature of the same spirit who appoints to the planets their pathway and controls the course of the suns and systems.

At this point it was, when we first encountered the root as a distinct organ in plant life, that it appeared opportune to enlarge somewhat concerning its structure and function. It would not be so convenient here to make any general comment upon the stem and its function, both because the subject is a larger one, and because it is in this part of the vegetable kingdom in what we may call an early and imperfect stage of its development. It will, therefore, be a preferable course to take a general view of those classes which were mentioned as succeeding to primitive ones in superiority of rank. The moss, as was said before, succeeds to the lichen. This process we can see going on before us. The one is the forerunner of the other and prepares for its support, as certainly as though consciously aiming at that end. For the under surface or root-face of the lichen has the power of slowly disintegrating the stone it grows on, and in course of time by absorption from the atmosphere and from elements acquired from rains, and other sources of moisture, and finally by the decay of the lichen itself, a soil is prepared capable of supporting a moss. Nor does this moss exist for itself alone. By its method of growth, which Mr. Ruskin has lovingly discovered and described, it accumulates by the decay of its lower leaflets a deep rich mould, wherein it flourishes, but wherein in due time alights also the spore of the fern, which declares itself heir to the legacy of the moss. Such may the historical succession of plants even on one spot be ascertained and observed to be. These lowly mosses and lichens are the true elves and fays of the woods, decking it with delicate tissues from their secret looms, dyeing it with sweet and brilliant colours in their viewless vats. Benign sprites they are and innocent, though they possess the power of ploughing the rock and reaping the stone. How the moss seems bent on padding and cushioning the hard stone, lest even a falling bird should be bruised thereon! If it had but its way, earth would be carpeted till silent to the tread as a mosque. Nowhere throughout creation do we find a finer, more exquisite workmanship than among the mosses. We call them velvet only because we can find no better and fuller expression. Who has not seen slanting sunlight enfilading a moss-grown wall, striking the myriad tiny stems of the moss into lustre as of silk and splendour, as of burnished bronze, till the old wall seems transfigured in a glory of chrysophras? Such sights seem to unveil for a moment the divinity of the universe: yet some would have us believe that these things were in no wise made for beauty nor for the delight of man.

Perhaps it may be thought that this last sentence implies a libel on those at whom it is aimed, but the following quotation from the 'Origin of Species,' gives it ample justification. Mr. Darwin says of "some naturalists" who object to his utilitarian doctrine, "They believe that many structures have been created for beauty in the eyes of man, or for mere variety. *This doctrine, if true, would be absolutely fatal to my theory.* Yet I fully admit that many structures are of no direct use to their possessors." Here, with a resolution almost dogged, Mr. Darwin places his back against his utilitarian theory, and stands grimly at bay against every admirer of nature and votary of the beautiful who may gather together against him. The very audacity of the position must embarass his opponents. It is like a man stepping out into the blaze of noon-day, and declaring there is no sun. What by-stander would attempt argument? That natural objects are for the most part beautiful, is a proposition that can hardly be denied, and will be most enthusiastically affirmed by those who have most closely studied nature from the æsthetic or artistic stand-point. If, then, we are to agree with Mr. Darwin, we must suppose that all this beauty has arisen incidentally and accidentally, without design or purpose, and this supposition is surely all but absolutely incredible. The truth is, and this is what misleads a one-ideaed observer, that in the architecture of nature, as in that of man, the useful and the beautiful are indissolubly connected. Discover, if you can, the most thoroughly convenient and serviceable form for any article, and depend upon it it will also be the most truly beautiful. We must not of course confound the ornate with the beautiful, or the ugly with the simple. Ornament is but an apology for the lack of that beauty which a completer fitness and finish would have bestowed. True is it that beauty unadorned is adorned the most. The human figure as we have it idealized in the marble of the sculptor is more beautiful than any costume can make it. Take also, as another example, that vessel best-fitted, by avowed means for traversing the ocean with safety and with swiftness. Look at a clipper-yacht running before the wind or cunningly slipping up sideways against it. As a study of clear and sweet curvage, sharp and clean meeting and crossing of straight lines, and grace of motion, nothing out of nature itself can excel it. So in nature fitness, which is here but a synonym for usefulness, goes hand in hand with beauty. But still nature evidently regards beauty also. If not, why so careful the external aspect of an animal should be so much more seemly than its internal? Why should plants hold aloft their flowers, as though in triumph at their own beauty? Why should——but one might ask many such questions. Suffice it to say that if Darwin stakes his theory on such an issue, and he avowedly does, the first snowdrop of spring shall confute him and the lowliest daisy look denial in his face.

And now, although so little of my subject is exhausted, it is time for us to draw it to a conclusion. I have endeavoured to point out and illustrate the different phases of force manifested in the external universe. After a brief notice of the mechanical and the chemical we proceeded to the vital which has since engaged our attention, and it will be always out of our province here to refer to those higher phases which are called mental and spiritual. Already we have, I think, seen sufficient evidence to warrant us in maintaining the position that vital phenomena are distinct in kind from mechanic and chemic, and cannot be regarded as the product of one or both of these. I have given you my opinion on the state of the great evolution question, to the effect that while the earth does seem to have arrived at its present condition by a gradual process, this process has not been satisfactorily accounted for by the automatic theories of Darwin and his followers. We then began to pass in review some of the lower orders of vegetable life, and marked their offices in preparing for higher forms or assisting their decomposition, and the utilization of the materials of which they were built up. Thus we saw that although in one view each organism struggles to maintain itself, yet whether wittingly or unwittingly, it subserves nobler ends and paves the way for the approach of higher forms. We saw also that dim instincts for order and beauty exist even in these lower organisms, and that the aims are attained to a remarkable degree. But, while yet occupied in tracing the beginnings of these vegetable aspirations, we find our allotted space of time is nearly exhausted. So for the present I would leave the subject, trusting that through your indulgence I may have another opportunity of pursuing it. But ere I release you, in case no other occasion should come, I would like to say that I fear there is little really fresh in thought in this paper. I am very largely indebted to the influence of other minds. To the American philosopher, Emerson, and to our Scotch philosopher, Dr. Hutchinson Stirling, I feel I owe largely, less perhaps on this occasion to the former than to the latter, who has made more energetic and effective attacks on the mechanical and materalistic schemes of modern scientists than any writer I am acquainted with. For matters of fact I had recourse to what I considered standard authorities. With this confession I will conclude.

On the motion of Mr. A. Noble, seconded by Mr. F. Schenck, a hearty vote of thanks was accorded to Mr. Baildon for his interesting paper.

The Honorary Secretary intimated the following donations to the Museum, viz., Seventeen specimens of Drugs, etc., chiefly from India, from the Society in London; Specimens illustrating the manufacture of Copper; Specimens of preparations of Lead used in the arts, from Mr. F. W. Pittuck, Hebburn.

Provincial Transactions.

GLASGOW CHEMISTS AND DRUGGISTS' ASSOCIATION.

The fifth meeting of the session of this Association was held on Wednesday evening, 14th February, in Anderson's College, George Street. Mr. D. Frazer, President, in the chair. The minutes of previous meeting having been read and approved of, donations were announced from Mr. John Henry, wholesale confectioner, Dr. A. M. Robertson, and the Secretary (Mr. J. M. Fairlie). Several new members were also proposed, after which, in the unavoidable absence of Dr. Machattie, F.C.S., the President delivered a popular lecture, entitled "Man and his Servants," in the course of which he gave a racy and entertaining sketch of the ancient "elements" fire, air, earth, and water, and their relation to man physically, socially and morally. At the close of the lecture, on the motion of Mr. Kinninmont, Vice-President, Mr. Frazer was awarded a hearty vote of thanks. At the opening and close of the evening's proceedings, Mr. John E. Fairlie exhibited a number of interesting objects by the aid of the microscope.

On the 14th inst. the sixth meeting of the session was held in the same place, Mr. Kinninmont, Vice-President, in the chair. The secretary (Mr. Fairlie), on behalf of Mr. Samual McCall Frazer, presented the Association with one of Messrs. Southall, Brothers and Barclay's "Students' Materia Medica' Cabinets." Mr. Kinninmont on behalf of the Association accepted the donation and moved that the best thanks of the Association be given to Mr. Frazer for his donation, which was agreed to by acclamation. Dr. A. T. Machattie, F.C.S., was then called upon, who delivered the last of his short series of lectures on "Modern Chemistry."

The following is an abstract of the lecture:—

The foundation of chemical science is obviously what is called chemical affinity, chemical attraction, or sometimes, *chemism*. This particular force, whatever it may be, seems to differ in some respects from all the other forces: gravitation, cohesion, adhesion, electricity, magnetism, etc. Notwithstanding the distinctions observable in these different forces, the opinion is growing among scientific men that all kinds of force are in some way connected, although we are at present ignorant of a principle common to all. In short, that the force which we call gravitation, acting throughout space and at immense distances, is not in essence different from the chemical force which unites atom to atom, and seemingly acts at distances almost infinitely small.

That substances combine with one another chemically is an elementary fact. That they always combine in definite proportions, when forming the same kind of compound, is a great advance in our knowledge, mainly due to Dalton, but foreshadowed to some extent by Wenzel and Richter, by experimenting on the double decomposition of salts.

Dalton's *atomic theory* assumes that the atoms of elementary, or so called elementary bodies, have a definite weight. The elements may not be simple substances; all we know is that they have not yet been decomposed. Indeed there is a possibility, even a probability, that there is only one kind of matter; and that the substances which we now regard as elements, may be special groups of atoms, which we have no means of decomposing. Speculations on the existence of an *ethereal medium* throughout space, conveying heat and light by undulation, but inappreciable by any other means yet discovered, favour the idea of the unity of matter, just as the correlation of the physical forces point to a unity in motion.

The question of deciding the atomic weights of the elements is one of vital importance in chemistry, and is by no means easy. Indeed lately several of the atomic weights have been altered, and the alteration has given rise to much confusion in text-books. Some chemists retain the old numbers as a matter of convenience merely; others use the new because they believe them to be correct; and others again, using both systems, introduce formulæ to illustrate the constitution of compounds, which still further increase the complication.

The atomic weights given for the elements are, of course, only relative. We do not know the weight of any atom. Hydrogen has at any rate the *lowest* atomic weight, or as we may more safely say, *combining proportion*. Hydrogen is accordingly taken as the standard, and its atomic weight regarded as one. In France, oxygen is the standard, and its atomic weight considered one hundred.

How are atomic weights determined? There are several means used to control the results.

Chemical considerations must necessarily be of most importance. Physical considerations are nevertheless of great value.

The expression *atom* is to be held to mean the smallest amount of any element which can exist in combination. This definition distinguishes the term atom from molecule; the latter term has two meanings: thus, a molecule of an element is the smallest amount which can exist in a state of freedom. The molecule of a compound should contain the smallest number of atoms of all its constituents which can enter into, or result from, a reaction.

Keeping close to hydrogen as one and our standard, for reasons which will become plain, we take for explanation of this atomic-weight question certain typical compounds, all of which contain hydrogen. These are hydrochloric acid, water, ammonia and marsh gas. Their symbols are, respectively, HCl, H_2O, H_3N and H_4C.

Is there any substantial chemical reason why they should be so represented? How do we arrive at the conclusion that these four compounds contain one, two, three and four atoms of hydrogen, and only one atom of each of the respective elements in combination? We cannot divide the hydrogen in hydrochloric acid. We can divide the hydrogen in water into two parts; in ammonia into three; in marsh gas into four. This is one of many chemical reasons, but applies only to the hydrogen of the above compounds. But if hydrogen be considered one, we find that no compound containing hydrogen can be produced or result from any chemical reaction which contains less than 35·5 parts of Cl; 16 parts of O; 14 parts of N; or 12 parts of C. We have thus one reason why these numbers may be considered the atomic weights of chlorine, oxygen, nitrogen and carbon.

Physical reasons may now be brought in to assist us.

Hydrogen, chlorine, oxygen and nitrogen are gases. The volume occupied by a gas (an elastic fluid) depends on temperature and pressure. Suppose we take one grain of hydrogen at any given temperature and pressure, and find the volume it occupies. We then try, at the same temperature and pressure, how much of the above remaining gases we can put into the same space. The result will show, 35·5 grains of chlorine; 16 grains of oxygen, and 14 grains of nitrogen. This cannot be considered a mere coincidence. Again, if we decompose hydrochloric acid, water, ammonia, and marsh gas—all in a gaseous state, and at equal temperatures and pressures—we get one, two, three, and four volumes of hydrogen in the respective compounds, and only a single volume of chlorine, oxygen, and nitrogen.

Carbon is never gaseous as an element, so we can only use the above experiment inferentially with regard to it.

Another means of controlling the accuracy of atomic weights, is the determination of the *specific heats* of the elements. The specific heat of any substance is the amount of heat required to raise a given quantity of it, equally in temperature, with the same weight of water. The unit usually taken in this country is the amount of heat required to raise one pound of water, one degree Fahrenheit. The French unit is different, but the principle is the same. If we take *equal* weights of the elements and determine their specific heats, they differ greatly; but if we take weights proportioned to what we call *atomic* weights, and determine the amount of heat required to raise them 1° F., we find a remarkable agreement. Practically, if the atomic weights of the elements be multiplied by their specific heats, the resultant number is *the same*, affording another means of corroboration.

Lastly, *isomorphism* assists in the determination of atomic weights. This means of control applies principally to compounds, and through them to their constituent elements. Thus the various *alums*, from their isomorphic character, assist in determining the atomic weights of aluminum, chromium, iron, etc., etc.

It may be here observed that when the atomic weights of a few elements are determined with all the certainty which the means at our disposal admit of, the atomic weights of the rest are more readily obtained; just as in a dissected map, whenever the position of a few pieces is ascertained, the completion of the problem becomes easier and easier as the progress proceeds.

The position that compounds occupy in relation to the present question has now to be considered. To find out this we must reverse our mode of examination. We wish to produce HCl, H_2O, and H_3N from their constituent gases. We take volumes in accordance with the numbers represented, and combine these to observe the result. Strange to say, though we *begin* with very *different* volumes, in every case we *end* with the *same*.

The resulting volume is always *double* the volume occupied by our standard volume of hydrogen. From this we derive the conclusion that the volume of a molecule of a compound volatile substance is *twice* the volume occupied by an atom of an elementary gas at the same pressure and temperature. Also that whereas the density or specific gravity of the gaseous *elements* is in direct proportion to their atomic weight, the density of a gaseous compound body is one-half of the sum of the atomic weights of its various constituents.

In order to bring elementary and compound substances into comparable relations, it is customary to consider elements, when free, to be in the molecular condition, a molecule of an element consisting of two atoms. A remarkable fact in connection with this view is what is termed the *nascent state* of elements. Illustrations of the nascent state may be taken from the extraordinary reducing power of hydrogen, and the oxidizing power of oxygen, provided that they are brought in contact with the substance to be acted on at the time of their production. They then exhibit a chemical action which they lose at once when free. It would appear from this that atoms of the same substance do combine, and in combining lose some of their previous activity. Hence the probability of the distinction between the atom and molecule of elements.

Seeing that compound volatile substances occupy the double volumes, it will be evident that their specific gravity is a most important control in determining their composition.

Atomicity or *quantivalence* next requires a short reference. These terms mean atom-fixing power. Hydrogen being our standard; chlorine, oxygen, nitrogen, and carbon obviously differ with respect to this power, and in the proportions of 1, 2, 3, and 4 respectively. According to the phraseology adopted, they are called monatomic, diatomic, triatomic, and tetratomic—or univalent, bivalent, trivalent, and quadrivalent. Attention to this curious feature in elementary substances has led to many important results.

It must be stated that there are exceptions to all the rules which have been referred to. Many substances may stand most, but not all, the tests applied. In such cases the balance of evidence must be struck, and characters of inferior value must subordinate themselves to those of more importance.

The exceptions, however, deserve great attention, whether the cause of their divergence should ever be cleared up or not. Indeed, having the general rules in our mind, it is easier to remember the rules by the exceptions than the exceptions by the rules. We may here apply the illustration of the parable of the lost sheep, and give ourselves far more trouble to find out the solitary instance that has strayed from the usual path, than bother ourselves about the ninety and nine that are securely locked up in their proper pen at home—our brains.

At the close of the lecture Dr. Machattie was awarded a hearty vote of thanks. The secretary then intimated that the examination of the tutorial and chemistry classes for the prizes offered by the council would take place on the 27th inst., and that arrangements were in progress for the botany class being commenced under the superintendence of Professor Keddie, who had so successfully conducted it during the two previous sessions. Several new members having been enrolled the proceedings terminated.

CHEMISTS AND DRUGGISTS' TRADE ASSOCIATION.

At a joint meeting of the Law and Finance Committee held at the office of the Association, 23, Burlington Chambers, New Street, Birmingham, on the 16th inst., the following resolutions were unanimously passed:—

Moved by the President, seconded by Mr. Hampson, and resolved:—"That the Solicitor be instructed to take all necessary steps to appeal against the decision in the case of the Apothecaries' Company *versus* Shepperley."

Moved by Mr. Southall, seconded by Mr. Churchill, and resolved:—"That the Solicitor be directed to instruct two leading counsel and a junior to undertake the argument on the appeal."

Moved by Mr. Barclay, seconded by Mr. Churchill, and resolved:—"That a full report of Mr. Shepperley's case be printed and circulated to each chemist and druggist on 'Kelly's Chemists' Directory.'"

Moved by Mr. Barclay, seconded by Mr. Churchill, and resolved:—"That the Solicitor be instructed to write to the Apothecaries' Company, calling their attention to the fact that other proceedings in their name are threatened, and requesting them to withhold their authority from all such proceedings until the legal status of chemists and druggists under the Apothecaries Act, 1815, is determined by an appeal to the Queen's Bench Division of the High Court of Justice against the decision in Mr. Shepperley's case."

Moved by Mr. Hampson, seconded by Mr. Barclay, and resolved:—"That the Secretary be instructed to collect further evidence of infringements of the Pharmacy Act, 1868, and to forward the same to the Registrar of the Pharmaceutical Society."

LEEDS CHEMISTS' ASSOCIATION.

The sixth general meeting of this Association for the present session was held on Wednesday evening, March 11th; the President in the chair; when, after the minutes of the previous meeting had been read by the Secretary, a paper was read by Mr. George Ward, F.C.S., entitled "Notes on some of the Ethers." He first drew attention to the simple ethers, showing very clearly by the aid of styptic formulæ the close analogy between the ethers and the metallic oxides of mineral chemistry; and that just as these oxides are related to the hydrates, so the ethers are related to the alcohols. The modes of preparation were then noticed; especial attention being given to the continuous process of the Pharmacopœia, the chemical changes taking place being lucidly explained by formulæ. The haloid ethers were shown to be exactly similar in constitution to iodide of potassium and other haloid salts, and the action of these haloid ethers upon the sodium compounds of the different alcohols was explained as the process for preparing mixed ethers. The frequent occurrence of the compound ethers in natural products, as the odour of wines and as the principal constituents of oils and fats, was also noticed, and specimens of these compound ethers employed as flavourings were exhibited.

A cordial vote of thanks was passed to Mr. Ward at the conclusion of his paper on the motion of Mr. Brown, seconded by Mr. Pick.

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, March 15. Professor Abel, F.R.S., in the chair. The visitors having been announced and the minutes of the preceding meeting read and confirmed, the names of Messrs. Carl T. V. Buch, H. Senier, S. G. Thomas, J. H. Poland and J. Y. Buchanan were read for the first time. Mr. Frank W. Young was elected after his name had been read the third time.

The first paper "On Isomeric Nitroso-Terpenes," by Dr. W. A. Tilden and Mr. W. A. Shenstone, was read by the Secretary. After alluding to the former paper by Dr. Tilden on the same subject the authors describe the methods they now employ for the preparation of the nitroso-chlorides of the terpenes, and which consists in passing gaseous nitrosyl-chloride into a well cooled mixture of the terpene with chloroform or with ordinary spirit, when the new compounds usually separate in the crystalline state. In this manner nitroso-chlorides have been obtained with the terpenes from both dextro- and lævo-gyrate turpentine oils, from oil of sage, and from oil of juniper; it is an important fact that although all these terpenes differ widely in their action on polarized light and in their other physical properties, yet the nitroso-derivatives, obtained by the action of alcoholic potash on the nitroso-chlorides, are all without action on polarized light, melt at the same temperature, and agree, apparently, very closely in their crystalline forms.

The nitroso-chlorides of that class of terpenes boiling at about 175°, of which hesperidene from orange peel oil is a type, were also examined; crystalline compounds being obtained from hesperidene, oil of caraway, bergamot, and, with some difficulty, from essence of lemon. The nitroso-chlorides from the two first when carefully heated in small quantities at a time yielded crystalline nitroso-derivatives, although none could be obtained by the process found to answer so well with the terpenes of the first class, namely, treatment with alcoholic potash. The authors believe that this method will not only serve to discriminate the different isomeric terpenes, but also to show that a large number of the natural terpenes are merely physical isomerides and not distinct chemical compounds.

Professor Maskelyne said he was engaged in examining the crystalline forms of the substances described in this paper, but the investigation was not yet completed. He might say, however, that the crystals from the first group of terpenes, although at first sight they appeared very different, seemed really to belong to one and the same system. The crystals from hesperidene and caraway were very simple, and had very few faces to them, but he believed they belonged to a different system from the other group.

The President having thanked the authors, Dr. J. H. Gladstone read a paper, by himself and Mr. A. Tribe, on the "Preparation of Copper-Zinc Couples." The object of the numerous experiments detailed in this paper was to ascertain the best formula for the preparation of the couple; and for this purpose it was necessary to ascertain the influence exerted both by the proportion of copper deposited on the zinc foil, and also by its state of aggregation, the latter varying with the strength of the solution of copper sulphate employed to attack the zinc. The results showed that the couple of maximum activity was obtained by depositing the copper from a two per cent. solution of the sulphate in six successive depositions, if it was to be employed in the decomposition of water, or for preparing ethyl hydride from a mixture of alcohol and ethyl iodide. For dry couples, however, such as those used in the preparation of the organo-zinc compounds and similar reactions, one deposition from a two per cent. solution was found to be most effective. The activity of these couples, from the results of experiments instituted with that object, was ascertained to be more than one thousand times greater than that of pure zinc. This paper was illustrated by numerous experiments.

The President said the authors had brought before them so many interesting results during the last few years, in connection with the copper-zinc couple, that their best thanks were due to Dr. Gladstone and Mr. Tribe for the lucid and precise details they had given them that evening as to the best way of making the most effective couple.

In reply to a question by Dr. Wright, as to whether other copper salts had been tried for the preparation of the couple, and if so, whether the conditions of maximum activity were the same, Dr. Gladstone said experiments had been made with other salts of copper, but not quantitatively, the object being to ascertain the best way of making the most active couple, so that copper sulphate was used as being most convenient.

Mr. Kingzett said that Dr. Paul, who had used the copper-zinc couple for estimating nitrates and nitrites in waters, had found a great difference in the results obtained with couples prepared with solutions of copper sulphate of different strengths.

Mr. E. Riley then gave a short account of "Chromium Pig-Iron." A quantity of pig-iron, which has recently been made in Australia, instead of having the ordinary qualities of pig-iron, was found to be exceedingly hard, and to present the appearance of the specimen exhibited. The ore employed in the manufacture had been analysed in this country by six or seven different chemists, all of whom, with one exception, had overlooked the presence of chromium, which might perhaps be accounted for by the fact that the specimen of ore sent over contained but a mere trace of chromium. The pig-iron from this ore, however, contained 6 to 7 per cent. of chromium, as might be seen from the analysis given of two samples

	I.	II.
Chromium	6·986	6·287
Carbon	4·418	4·200
Silicon	1·460	·976
Sulphur	·102	·207
Phosphorus	nil	·055
Iron	—	88·343
Manganese	·125	nil.

From this it could readily be seen that the relation between the amount of carbon and sulphur was quite abnormal.

As some 1200 tons of this iron had been manufactured it was important to know what to do with it. It had been stated that chromium plays the same part as manganese in iron, but in experiments made to ascertain if this chromium pig-iron could be substituted for speigeleisen in the manufacture of Bessemer steel, very unsatisfactory results were obtained, the steel breaking up under the hammer. When mixed with one-half hæmatite and puddled it melts with difficulty; but although the chromium soon goes out in the cinder, the iron produced would not weld.

The President said Mr. Riley's communication possessed considerable interest, but he himself should have considered it very unlikely that this chromium iron would play the part of spiegel-eisen. He had examined a specimen of the so-called chromium steel, but had found a mere trace of chromium in it. It was possible, however, that the chromium exerted a function in the production of the steel, but was eliminated at some stage in the process, so that it did not appear in the finished steel.

Mr. Riley, in answer to some remarks on the subject, expressed his opinion that the colour test, although it could be depended on for the determination of the amount of carbon in steel, was very untrustworthy when applied to iron, the determination of the carbon by combustion after removal of the iron being the most reliable. He had found that the chromium had dissolved with the iron during the ordinary treatment for analysis.

Mr. C. E. Groves then read a "Note on Gardenin" by Dr. J. Stenhouse and himself. Gardenin was discovered by one of the authors some twenty years ago in "Dikamali gum," an Indian drug, but the quantity obtained at that time was too small for analysis. Recently, however, they have obtained a larger specimen of the resin and extracted the gardenin from it. It crystallises in deep yellow needles, which melt at about 164° C., and are somewhat difficult to purify. The results of the analysis agree very well with the formula $C_5H_5O_2$, which requires 61·86 per cent. carbon, and 5·15 hydrogen, whilst the numbers obtained by Flückiger were 59·47 C. and 6·71 H. It is probable, however, that the specimen he analysed, and which melted at 155°, was contaminated with a colourless fatty substance of low melting point, present in the gum, and which is not entirely removed even by repeated crystallization from spirit. The authors find when gardenin is dissolved in glacial acetic acid, and carefully treated with nitric acid in the cold, that a red crystalline substance is formed which melts at about 236°. It crystallises in long needles, which are insoluble in water and almost insoluble in alcohol. As it is insoluble in dilute acids, but soluble in dilute alkaline solutions, from which it is reprecipitated on the addition of an acid, it has been provisionally named gardenic acid. The authors hope soon to be in possession of a large quantity of Dikamali gum, which will enable them to continue this investigation. A note on ginger was appended to this paper, in which it is shown that the resin in ginger, when fused with an alkaline hydrate, yields protocatechuic acid.

After the president had thanked the authors in the name of the fellows, the secretary read two papers by Mr. M. M. P. Muir, the first of which was an "Additional Note on a Process for Estimating Bismuth Volumetrically," in which the author gives a modification of his former process. He now precipitates the acid solution of bismuth nitrate with excess of sodium acetate, dissolves the precipitate by means of a slight excess of acetic acid, and titrates with a standard solution of potassium dichromate. The second paper was "On certain Bismuth Compounds, Part IV.," in which a chromate of bismuth $3Br_2O_3$, $2CrO_3$, is described as obtained by the action of a hot potash solution on the chromate, $3Bi_2O_3$ $7CrO_3$. The formation of the compounds $Bi_2O_5+H_2O$, and $Bi_2O_4+H_2O$, by the action of bismithous oxide suspended in a hot solution of potassium hydrate, is then considered, and it is also shown that the oxide $Bi_2O_5H_2O$, when dissolved in an acid, and precipitated with an alkali, always yields bismuthous hydrates, $Bi_2O_3+H_2O$, whether the solution has been previously subjected to the action of reducing agents or not. The author concludes this part of his paper by discussing the formula of the six known hydrates of bismuth. There is an addendum on the action of potassium ferrocyanide on bismuth solutions, from which it appears that in presence of nitric acid, bismuth ferrocyanide, Bi_45FeCy_6, is first produced, quickly passing, however, into the ferrocyanide Bi_35FeCy_6, which in turn undergoes decomposition with evolution of hydrocyanic acid.

The concluding paper "On the Determination of Urea, by means of Hypobromite," by Dr. M. Simpson and Mr. C. O'Keeffe, gives a description of a form of apparatus devised by them, of which it would be very difficult to give an intelligible account without reproducing the drawing which accompanies it. It does not seem to be so convenient for hospital practice, however, as that recently described by Dr. Dupré.

The meeting was then adjourned until Thursday, the 29th March, the anniversary. The next ordinary meeting will be on Thursday, 5th April, when Professor Nevil Story Maskelyne will deliver a lecture "On the Discrimination of Crystals by their Optical Characters."

PHILADELPHIA COLLEGE OF PHARMACY.

A meeting of this Association was held on February 20th, Mr. Robert England in the chair.

Mr. A. W. Miller presented a specimen of oil of cubebs, prepared by percolating the ground drug with light petroleum benzin, permitting this to evaporate spontaneously, and then subjecting the residue to distillation. The product was entirely free from all odour of petroleum. About 3 lbs. of essential oil were obtained from 25 lbs. of the drug, and about 20 ounces of resin, fatty oil, etc., were left in the still.

Mr. E. Gaillard read a paper on "Dr. Davy's Method of Detecting Arsenic by the use of Amalgam of Sodium."

Mr. A. W. Miller presented a specimen of so-called berry wax, the product of *Myrica cordifolia*, from Cape Town, Africa. The wax is of a dull greenish colour, closely resembling in its general appearance the myrtle wax of the United States.

Professor Maisch read the following note—

ON THE DETECTION OF CASTOR OIL IN COPAIBA.

At the last meeting I incidentally remarked (*Amer Journ. Pharm.*, 1877, p. 84), that the test for the detection of castor oil in copaiba by petroleum benzin, as proposed by Professor Wayne, was fallacious. The test is recommended to be applied (*Ibid.*, 1873, p. 326) by shaking the suspected balsam with three times its volume of petroleum benzin, when, if castor oil be present, a milky mixture is stated to be formed, separating quickly into two layers, the lower containing all the castor oil. Having often repeated this experiment with different copaibas mixed with their own bulk of castor oil, an absolutely transparent solution was always obtained with three or four volumes of petroleum benzin, and the solutions remained clear and free from sediment after standing for several days and even weeks. Mr. Charles A. Bowman, however, informed me that with larger quantities of the benzin, a separation of the castor oil from the copaiba could be effected, and that copaiba alone would yield with sufficient petroleum benzin a turbid mixture from which a flocculent precipitate would subside.

On dissolving a pure copaiba in petroleum benzin it was found that with eight measures of the latter the solution was perfectly transparent. On the addition of another measure of benzin, a slight turbidity occurred, which increased with more benzin, but it took nearly a week before the liquid became clear again, depositing at the same time some transparent resinous matter. When the same copaiba had been previously mixed with castor oil, it required the same amount of petroleum benzin to produce a turbid solution, from which, in the course of twelve hours, an oily liquid had settled to the bottom, equal in bulk to the castor oil employed. But in the course of several days the lower layer, containing the castor oil, had increased to more than double the volume.

It appears from this that petroleum benzin may be used for the purpose indicated, if not less than *ten* volumes are employed, instead of *three*, as originally proposed by Professor Wayne. But it must not be overlooked that pure copaiba will also produce a turbid, though less opaque solution, and its separation and the examination of the lower layer may become necessary, unless a sufficient quantity of the castor oil to be remunerative to the sophisticator had been added, in which case the dense milkiness will at once indicate it.

Different kinds of copaiba will be found to show somewhat different behaviour. A sample has been handled by Mr. Bowman, which, with *six* volumes of the benzin, became turbid and *readily* separated floccules, while another, as stated before, acquired its maximum turbidness with *ten* measures of benzin, and *slowly* deposited a transparent resin; another kind, a Para copaiba, over sixteen years old, required fifteen measures of benzin before a slight turbidity was produced, and even after it had been mixed with its own bulk of castor oil the amount of benzin mentioned did not disturb it to a very appreciable extent. Professor Wayne, having operated with a sample from which the castor oil was separated by *three* measures of petroleum benzin, it is evident that the variations are very considerable, and it is not impossible that still greater ones may be observed with other kinds of copaiba.

Mr. R. V. Mattison stated that he had also tried the petroleum tests for copaiba, but had become quite confused by them.

Professor Maisch said that so far aqua ammoniæ was still the best test; he attributed the perplexing variation in the behaviour of the copaiba to its production from different botanical sources.

Notes and Queries.

[542]. MARBLE POLISHING POWDER.—Will any reader kindly give me information about a powder, used very largely for polishing marble and ornamental stones at Wareham in Dorsetshire, or how it can be obtained? W. B. C.

TABLES OF MATERIA MEDICA. A Companion to the Materia Medica Museum. By T. LAUDER BRUNTON, M.D., Sc.D., F.R.C.P., F.R.S., etc. London: Smith, Elder and Co. 1877. From the Publishers.

FOWNES' MANUAL OF CHEMISTRY, THEORETICAL AND PRACTICAL. Vol. I. Physical and Inorganic Chemistry. Twelfth Edition, revised and corrected by HENRY WATTS, B.A., F.R.S., etc. London: J. and A. Churchill. 1877. From the Publishers.

Obituary.

Notice has been received of the death of the following:—

On the 4th of March, 1877, Mr. Evan T. Prosser, Pharmaceutical Chemist, Witham. Aged 45 years. Mr. Prosser studied in the Society's laboratories during the Session 1853-54, and afterwards became Assistant to Dr. Stenhouse. He had been a Member of the Pharmaceutical Society since 1859.

On the 9th of March, 1872, Mr. Edward Merrikin, Chemist and Druggist, Lynn, Norfolk. Aged 51 years.

On the 9th of March, 1877, Mr. Robert Christopher Pitts, Pharmaceutical Chemist, St. Giles Street, Norwich. Aged 62 years. Mr. Pitts had been a Member of the Pharmaceutical Society since 1853.

On the 11th of March, 1877, Mr. Francis Hull, Chemist and Druggist, Leicester. Aged 86 years.

On the 12th of March, 1877, Mr. William Haythornthwaite, Chemist and Druggist, Kirkby Lonsdale. Aged 59 years.

On the 16th of March, 1877, Mr. Jabez Marlow, Pharmaceutical Chemist, Lees, near Oldham. Aged 46 years. Mr. Marlow had been a Member of the Pharmaceutical Society since 1853.

The following journals have been received:—The 'British Medical Journal,' March 17; the 'Medical Times and Gazette,' March 17; the 'Lancet,' March 17; 'Medical Press and Circular,' March 22; 'Nature,' March 17; 'Chemical News,' March 17; 'Gardeners' Chronicle,' March 17; the 'Grocer,' March 17; 'Journal of the Society of Arts,' March 17; 'Grocery News,' March 17; 'Produce Markets Review,' March 17; 'Educational Times,' for March; 'British Journal of Dental Science,' for March; 'Journal of Applied Science,' for March; 'American Journal of Pharmacy,' for March; 'Pharmacist,' for March; 'Canadian Pharmaceutical Journal,' for March; 'Moniteur Scientifique,' for March; 'Pharmaceutische Zeitung,' for March 17; Sanitary Record,' for March 17; 'Medical Examiner,' for March 17.

The Herbarium Prize.

Sir,—While the subject of the herbarium prize is under discussion, I should like to throw out a few suggestions concerning it.

The prize was originally intended to encourage the study of botany and "to infuse into the minds of our successors a due appreciation and a practical knowledge of the structure, characters, classification and properties of plants, especially those which are comprised in the materia medica."

It was believed that the collection of an herbarium would "oblige the student to acquire an acquaintance with the rudiments of botany," and that such knowledge would "greatly facilitate the study of plants more especially belonging to his department."

Now the conditions under which the prize is competed for contain one sentence the first portion of which appears to me to require considerable modification. That sentence is as follows:—

"In estimating the merits of the collections, not only will the number of species be taken into account, but also their rarity or otherwise and the manner in which they are preserved; and should a specimen be wrongly named it will be erased from the list."

This sentence means to the competitor, that he must collect as many plants as possible in the given time, and that if he lives in the richest botanical district, has the most time to spare and the deepest purse, he will infallibly carry off the prize from a less fortunate and poorer competitor. Is this right or fair? The result naturally is that only a few students feel they have any chance of obtaining the prize, and, consequently, but few compete.

The effect upon an intending competitor is as follows: He endeavours to collect as large a number of plants as possible. If he has but little time at his disposal he will dry them badly, mount them hastily, consequently carelessly, and name them from drawings of plants, without examining their structure or characters. Not only so, but all plants with small flowers, and which take much time to examine, are discarded, and thus the knowledge of the structure of such natural orders as Polygonaceæ and Euphorbeæ is ultimately *nil*.

If the prize is really to do the good originally intended by its institution, it must be brought within the reach of a larger number of competitors, and the conditions attached to it, must require evidence of a practical knowledge of the structure, characters, and properties of the plants collected. I would suggest that if the necessary number of plants were very limited, say 150, and made to include all the indigenous medicinal plants in the district in which the competitor resided, a larger number would probably compete for the prize, and consequently more good would be done.

If the competitor were required to illustrate each species as thoroughly as possible, by as many varieties as he could meet with, and by dissections of a flower (and where possible a fruit and a root also), pasted neatly on the same sheet with the dried specimen; and to write the character by which each species is distinguished from another, at the bottom of the sheet, and to mention the properties of the plant; proof would be afforded that the specimens had been examined and understood, and that habits of careful and accurate observation had been commenced, and the competitor would have a small and most valuable collection of his own, even if he failed to win the prize.

The facts which it appears to me would be most worthy of being taken into account in adjudicating the prize are, the time at disposal for study (guaranteed by the employer), the nature of the district in which the collector resides, and the thoroughness with which his botanical work has been done.

One more point suggests itself, and it is this:—The prize offered for an herbarium is not a commensurate reward for the trouble taken. The collection of an herbarium in one year implies a very considerable expenditure of money in paper and travelling; and the chance of obtaining a bronze medal, or perhaps nothing at all, is by no means an inviting prospect. For my own part, I know that I should have considered such works as Bentham's 'Flora' and Sowerby's 'Grasses' a more valuable reward than a medal.

A Former Competitor.

Chemists and Druggists' Association.

Sir,—In the report of the Meeting of the Executive Committee of the Chemists and Druggists' Association, held in Birmingham, 28 Feb., 1877, which appeared in this month's *Chemist* and *Pharmaceutical Journal* of the 17th inst., I am reported as "A member of the Sub-Committee for making arrangements for the Annual Meeting in London."

Allow me to say my name is inserted without my consent.

I have from the first declined taking any official position in the movement, for reasons which I have assigned when applied to on previous occasions.

Benjamin Humpage.

Turnham Green, March 20, 1877.

Earthenware Measure Cups.

Sir,—Throughout the country chemists and druggists will welcome the appearance of Messrs Proctor and Sons' new earthenware measure cups, which combine, as mentioned in the published prospectus, accuracy, simplicity, and cheapness.

These unique little vessels, however, are being sold without precise instructions as to how they are to be employed, and chemists will need to exercise care in wording the label required to be attached to each measure, otherwise confusion and mistakes may result from their employment.

From the advertisement and the words at present stamped on these cups, it is evidently the author's wish to discourage the term spoonful.

Inasmuch, however, as this term will long continue to be employed, it is, I think, very necessary that additional matter be stamped on these cups, in terms corresponding to those employed by the dispenser on the label of the mixture.

At present the patient may be instructed to take one tablespoonsful of a mixture, and the only means of recognizing the proper measure is the patient's ability to translate the term "half-ounce," which is stamped in black letters on the vessel.

The term "half-ounce," is to many quite unintelligible, and even were patients able readily to translate it, how few there are who would also know it corresponded to one accurate tablespoonful.

Certainly the dispenser in presenting the measure would remark that when filled to the inner rim it corresponds to the dose prescribed, but this would fail to prevent mistakes in cases where several measures of variable size had previously been supplied.

In conclusion, I would suggest that these measures, previous to being sent out, either be attached in some secure way to the bottle for which they are to be employed, or otherwise distinctly labelled (preferably stamped by manufacturer), somewhat as follows:—

"This medicine cup when filled to the inner rim holds one accurate tablespoonful."

The word "accurate" also to precede the word "spoon" on each label, that something different to the ordinary spoon be understood.

J. R.

Milk of Sulphur.

Sir,—Notwithstanding Mr. Chipperfield's tall writing on the subject of the milk of sulphur case, the purchaser got what he asked for,—the article that has been sold as milk of sulphur for thirty years. If there is any fault it is an error of manufacture, and not an adulteration, the latter being the addition of an inferior to a superior article for the purpose of obtaining an increased profit; therefore, under the Adulteration Act, the conviction was decidedly wrong. This argument might be used with advantage by counsel engaged in the appeal.

C. K. G.

Grayshott Road, S.W., March 20, 1877.

[*** Though we fully agree with our correspondent's opinion as to the legitimacy of selling as "milk of sulphur" the preparation made with lime, according to the directions of the London Pharmacopœia of 1721, we do not think the argument he suggests is of much value, and we should deprecate its application to the milk of sulphur case.—ED. PHARM. JOURN.]

TO THE BENEVOLENT.

Sir,—With your kind permission, I beg to submit the result of further efforts on behalf of Mrs. Fowler, the particulars of whose melancholy case appeared in the *Pharmaceutical Journal* of January 13th.

W. D. SAVAGE.

W. J. Cooper.—The formula for Ung. Althææ, P. L., 1746, is as follows:—

"℞ Olei e mucilaginibus M libras tres,
Ceræ flavæ P libram unam,
Resinæ flavæ P libram dimidiam,
Terebinthinæ communis P uncias duas.

Liquentur resina et cera cum oleo; deinde ab igne remotis adde terebinthinam, et, dum mixtura calida est, coletur."

"*Indiana.*"—You are recommended to apply to an export druggist.

W. Thirlby.—St. Mark's Hospital, City Road, London.

G. C. R. O.—The emulsion will not be satisfactory. As soon as the Mag. Sulph. is added to the emulsified Copaiba, the soluble potash soap which has been formed with the Liq. Potassæ will be decomposed, and an insoluble magnesia soap will result. A permanent and satisfactory emulsion may be obtained by placing in a mortar ℥ss of Mucil. Acaciæ with ʒij of Pulv. Acaciæ to thicken it, then adding gradually, with trituration, the Copaiba, and, if necessary, a drop or two of water during the trituration, to keep the mixture smooth and white. Next add water gradually to about ℥v., then the Liq. Potassæ and Tinct. Hyosc., afterwards the Potass. Bicarb., and lastly the Mag. Sulph., the last two being previously dissolved in a little water. This emulsion should be quite creamy, and should not separate.

"*Alpha.*"—The Ung. Hydrarg. Oxidi Rubri, diluted to about seven times its weight.

"*Dispenser.*"—(1) The swelling is due to decomposition of the iron salt and formation of ferric oxide. (2) The precipitation is due to the formation of an insoluble quinine salt with the tannin of the tincture; the bad smell is the result of fermentation.

"*Inquirer.*"—We are unable to suggest a substance that would increase the plasticity without interfering with the hardness. The specimen sent appears to be rather friable.

E. Atkins.—Hydrogen peroxide can be prepared from barium peroxide by the methods indicated in all works on chemistry.

X. Y. Z.—We are not aware that any patent right exists that would interfere with the sale of the article referred to.

Y.—The English Act is not in force there, and we believe the only Pharmacy Act regulating pharmacy in our Australasian colonies is that recently passed in New South Wales (see before, p. 318).

"*Reader.*"—The plan recommended by you is already carried out to a considerable extent. The newspaper particularly referred to shall be included in our list.

"*Ego Nescio.*"—Syrup of White Poppies is sometimes sold under the name.

J. A.—Linctus Glycerini Compositus, P. H. L.:—

Take of—

Muriate of Morphia	22½	grains.

Spirit of Chloroform	2½	"	"
Glycerine to	40	"	"

M.

J. N.—See the paper by Dr. Dupré in vol. vi. of the present series, p. 868.

The Prosecution of a Chemist and Druggist at Nottingham.—Correction.—Mr. John Horne Glaisyer writes to say that there is a mistake in the report of his evidence given in the *Nottingham Journal*, and copied into this Journal (before, p. 766). The date should have been 1816, and the evidence was to prove the custom of chemists and druggists previous and immediately subsequent to the Act of 1815.

A. J. S.—The colour would be due to the action of the mineral acids upon the nux vomica, and the reaction would probably be a complex one.

E. H.—We think the dose should be two tablespoonfuls. The question of the antagonistic action of the ingredients is one that must be left with the prescriber.

"*Lex Talionis,*" *F.C.S., and* "*One Who has Served behind the Counter Twenty-one Years.*"—We do not think the publication of these letters would serve any useful purpose. A reference to the judgment of Mr. Baron Bramwell will show that it has a wider application than our correspondents appear to be aware. We should recommend direct communication with the Council in reference to any course of action which it is suggested that body should take.

"*West End Chemist.*"—We share your objection to underselling, but it is evident there is a difference of opinion as to the price at which patent medicines should be sold.

"*Statim,*"—The article referred is a proprietary preparation of which the formula has not been published.

H. W. Thorburn.—The chlorate of potassium is decomposed by the sulphuric acid and the sugar is oxidized by the products of the chloric acid liberated.

NOTICE.—Considerable inconvenience and disappointment are frequently caused by neglect of the regulations as to correspondence, letters intended for the Editor being sent to the Publishers or the Secretary, and *vice versâ*. A compliance with the explicit instructions published weekly over the Editorial columns will prevent delay, and the consequent annoyance.

COMMUNICATIONS, LETTERS, etc., have been received from Dr. Hesse, Mr. Wills, Mr. Bell, Prof. Dymock, Mr. Codd, Mr. Home, T. A. H.

"THE MONTH."

The cold frosty weather which has characterized the present month has somewhat hindered the progress of vegetation, and it is only during the last few days that the buds of the lilac and hawthorn have burst open, and that the signs of spring have commenced in earnest. Still, there are a few medicinal plants in bloom to be found in the woods and hedges in the country by those who have the courage to look for them. In almost any chalky wood south of Durham, and often in copses and thickets on other soil, may be found the dark shining evergreen leaves of the spurge laurel (*Daphne laureola*, L.), with its short racemes of sweet-scented green flowers nestling among the upper leaves. The plant is well named, for it has much the appearance of a small laurel, while the leaves have the peculiar oblanceolate shape of the wood spurge (*Euphorbia amygdaloides*, L.). The flowers are often polygamous; some staminate flowers, which may be distinguished by having the tube of the flower longer than the others, being found intermixed with the perfect ones. It may be here noticed that each flower consists of a single whorl of leaves, which by some botanists is called a calyx and by others a perianth—perianth is, however, the term more generally used. The perfect flowers will be found to exactly resemble in internal structure those of the mezereon (*Daphne Mezereum*, L.), having eight stamens arranged in two rows, and a superior ovary. The bases of the flowers are furnished with concave scaly bracts.

The dandelion (*Taraxacum Dens Leonis*) is now in full blossom, and although so common a plant is not undeserving of notice. The leaves are remarkable as affording one of the best instances of the runcinate form. Careful observers will notice several varieties of this plant; one of these has leaves so much narrower and more deeply cut than the common form, that if not in flower it might be supposed to be a different species; another growing in boggy places has the leaves almost entire and the outer scales (phyllaries) of the involucre ovate and pressed upwards. The plant is thoroughly cosmopolitan, being found in all four quarters of the globe. It is interesting as being one of the plants used by Linnæus to form a floral clock, its flowers opening between five and six in the morning and closing at nine o'clock at night; they also close during rain. Each of the heads consists of from 100 to 200 florets; these florets are abundantly furnished with honey, which rises high in the tube, so that it is a great favourite with insects, no less than ninety-three species of which were observed by Müller to visit the plant. The flower if not fertilized by the visits of insects has the power of fertilizing itself, the stigmas after a time curling over so as to touch the pollen. The root of dandelion should be compared with that of the *Hypochœris radicata*, a composite plant which has leaves and flowers resembling those of dandelion in size and shape, but the leaves differ in being rather rough and hairy and the flower stalk in being taller and having a few branches. The pappus affords an instance of what is known as pilose pappus, the threads being simple and unbranched. This is perhaps the best time of year to gather the root, as the juice is more bitter and the root contains less inulin than in the autumn, the period at which it is usually collected.

Another plant, of which little more than the name is at present retained in English pharmacies, may now be found decking railway banks and moist clayey places with its bright blossoms. The coltsfoot (*Tussilago Farfara*, L.) has a flower resembling the dandelion in shape and size, and might at a distance be easily mistaken for it, but upon a close inspection it will be seen that the flower-stalk (scape) is covered with scaly bracts, that the flowers appear before the leaves, and that the central florets in the capitulum are tubular, while in the dandelion they are all ligulate.

The green hellebore (*Helleborus viridis*) which must not be confounded with the green hellebore of America (*Veratrum viride*, Ait.) may now be found in blossom here and there in orchards and thickets. It is, however, by no means a common plant here. In Germany the root is used in medicine, and fetches three to five times the price of that of the black hellebore, from which it differs in being more bitter and acrid, and in containing more numerous drops of fatty oil. From the other British species, *H. fœtidus*, L., green hellebore is easily distinguished by its paler leaves, and large, open, entirely green flowers, of which there are usually two or three on the flowering stem. In *Helleborus fœtidus*, L., the leaves are dark green and the calyx is tipped with purple and is never widely open. In all the hellebores the petals are small and tubular like those of the Christmas rose.

Besides these two, another species, *H. orientalis*, may now be seen in blossom in the Botanical Gardens at Edinburgh by those who have the good fortune to reside in that city. This species is supposed to have been the hellebore of the ancients; it is said to be the most active, medicinally, of all the species. Its rhizome possesses the peculiarity of being easily peeled, a process which is impossible with *H. niger* and *H. viridis*. This species has usually two coloured flowers and *leafy* bracts.

On damp mornings during March and April the air in some places may be noticed to have a peculiar fragrance, due to the opening buds of the balsam poplar (*Populus Tacamahaca*), which are covered with a fragrant resinous exudation. This resin has the peculiar property, like benzoin, when boiled in lard of preventing it from becoming rancid. Its odour exactly resembles that of a Californian plant (*Eriodictyon californica*, Benth.) lately used in America as a remedy for bronchitis, and suggests that these poplar buds might be worthy of trial for the same purpose. The bark of another species is used as a tonic in America. Although a native of North America and Siberia, it is frequently to be seen in this country planted in avenues, or by roadsides and in gardens, and may be distinguished from all the British poplars by its larger ovate leaves and the different appearance of the branches. A resin called Tacamahaca, obtained from this tree in America, was formerly official in the Edinburgh Pharmacopœia.

The box tree (*Buxus sempervirens*, L.) may now be seen in flower, and is so common everywhere in gardens and shrubberies that it is easily examined, and although it has not very strong claims to rank as a medicinal plant, yet it presents many points of interest. It is the only native shrub which we possess belonging to the Euphorbiaceæ. The leaves have the epidermis quite loose and easily separable from the under surface, so that on breaking a leaf transversely and pressing it, the leaf forms a little bag. The flowers are peculiar among plants in this natural order in having petals. The little clusters of sessile flowers (glomeruli) open centrifugally; the central flower is a pistillate one, and is surrounded by a number of staminate flowers, the plant being monœcious. The pistillate flowers have a four-parted calyx and three petals, both of which are pale green and membranous, and the capsule has three short styles, each terminating in a bifid stigma; between the styles are three small yellowish fleshy glands. The staminate flowers have a three-parted calyx, two petals, four stamens, and an abortive pistil. Although the plant has apparently no odour, yet when growing in extensive patches, as on Box Hill, in Surrey, an exhalation of a peculiar urinous character is disagreeably evident. The plant contains an alkaloid (buxine) which is chemically identical with that of pareira brava and also with bebeerine. The medicinal action of the plant has been lately carefully investigated by Drs. Ringer and Murrell, a full account of which was published in vol. lix. of the 'Medico-Chirurgical Transactions.'

In the various botanical gardens the herbaceous grounds are still looking very desolate, with the solitary exception of the beds containing the Liliaceæ, Melanthaceæ and Amaryllidaceæ. The pretty little *Bulbocodium vernum*, with its naked lilac flowers, looking like those of colchicum in miniature, is almost the only garden representative of that order now in blossom; while the lovely blue flowers of *Scilla Sibirica*, the grape-like raceme of the starch hyacinth, and the solitary white flowers of the *Tritelia uniflora* are just beginning to enliven the Liliaceæ border. The latter flower is very singular on account of the flowers having a delicious odour of violets, while the stem when bruised exhales a most powerful smell of onions. The Amaryllidaceæ, on the other hand, are well represented; indeed, the coming month is the best in the year for the study of this group of plants, conspicuous among allied orders by the frequent occurrence of a corona in its flowers.

Through the kindness of Professor Balfour we are able to say that in the Edinburgh Botanical Gardens, the mandrake (*Mandragora officinalis*, L.) is now in bloom in the open ground, but under a glass frame. Although not used in the country, it yet undoubtedly possesses powerful properties; indeed, in olden times it was employed as an anæsthetic as chloroform is now. The plant has a strong family resemblance to belladonna in the shape of its flowers, but the leaves are arranged in a compact tuft at the root, and the solitary flowers arise from the tuft. From the occasional resemblance of its thick fleshy branching root to the trunk and limbs of a man, it was formerly an object of superstitious belief and was used as a charm to dispel demons and as a love philtre; indeed, it is supposed by some to have been the mandrake spoken of in Genesis, ch. xxx. In medicine it has been used as a hypnotic and as a resolvent for tumours, etc. Many curious legends are connected with this plant, some of which are scornfully alluded to in Gerarde's Herball. The root which is sometimes offered for sale by country people as mandrake root is that of *Bryonia dioica*, L. The rhizome of *Podophyllum peltatum* is sold in this country under the name of mandrake, or American mandrake root, by herbalists, and is what is generally wanted when mandrake root is asked for. Other plants now in blossom in the open air at Edinburgh are the three species of hellebore above alluded to, merzereon, elm, violet, dandelion and tacamahac poplar.

The hothouses at the Regent's Park Gardens now present a very brilliant aspect. The tree rhododendrons with their handsome tufts of scarlet or magenta coloured flowers, and the white and crimson camellias in full blossom, set off the dark green of the other shrubs, while the yellow blossoms of the narcissus, acacias, and genistas are tastefully arranged among the pink, red, white, blue, and deep purple of the hyacinths, the white and pink primulas, the azaleas of many hues, and the lovely cinerarias. One shrub, *Sparmannia Africana*, L., is particularly worthy of notice, from the beauty of its flowers and foliage, and the peculiar structure of the outer rows of stamens, which are sterile and covered with little swellings. The *Illicium Floridanum*, alluded to in January, may now be seen in full blossom in the larger conservatory. The only medicinal plant, however, of special interest, now in blossom at these gardens is the *Podophyllum peltatum*, L. The plant which is about a foot high, has two forms of leaves; those which do not bear flowers are distinctly peltate, and are deeply cleft almost to the middle into wedge-shaped lobes, which are again slightly lobed at the apex; the leaves which bear flowers are of the same height, but the stalk divides near the middle into two parts, each terminating in a leaf, and from the fork between these two leaves arises the solitary white waxy looking flower. The flower-stalk being shorter than the leaves, the flowers are somewhat hidden among the green leaves, with which they contrast very prettily. The leaves have a peculiar aspect, which once seen is not easily forgotten; the veins are much depressed and of a pale colour, which gives an appearance of convexity to the portions of the leaf between each vein.* The two leaves belonging to the flower-stalk are deeply divided on one side, often quite to the petiole, so that they are then not peltate, but rather pedatifid. It is noticeable that Hanbury and other botanists have placed this plant in Berberidaceæ, instead of Ranunculaceæ, on account of the petals being in a double row of three, the stamens definite in number (usually about 12), and the baccate fruit consisting of a single carpel. The plant may be looked upon as one of the links connecting the two families, since it has radiate-veined leaves, and anthers which dehisce longitudinally. While speaking of podophyllum it may be remarked that the resin met with in commerce under the name of podophyllum is very variable in appearance and even in specific gravity, and that the cause of this fact deserves investigation.

In the garden of the Apothecaries' Company at Chelsea the *Drimys Winteri* is now coming into blossom freely and is the only medicinal plant worth seeing there at present.

In the economical house at Kew, the coca plant is now full of buds and will during the next month be in full flower. Several varieties of orange, including the Seville and blood oranges, are now in full blossom, and the atmosphere there is redolent with the odour of neroli. The appearance of the orange flower is too well known to require much comment, but probably only a botanist would note that the stamens are arranged in a number of distinct bundles (polyadelphous) and arise from the base of a small white disc at the base of the ovary, the disc itself being moist with nectar; sometimes an inner row of stamens

* This appearance is well shown in Bentley and Trimen's 'Medicinal Plants,' pt. 9.

is present, and these appear to spring out of the disc, suggesting that the disc is, in this instance, a ring of suppressed stamens; neither the small five-toothed calyx nor the disc appear to enlarge during the growth of the fruit. The leaves are worthy of notice from the fact that the lamina or blade is attached by a joint to the top of the small leaf-like petiole, and that the leaf is an instance of the simplest form of a compound leaf, it being regarded as the terminal leaflet of a ternate or pinnate leaf, the other leaflets not being developed.

Several varieties of the tobacco plant may also be noticed in the same hothouse; these differ much in the shape and size of the leaves.

At Edinburgh the ipecacuanha plant may now be seen in perfection, having both flower and fruit; also the *Citrus medica*, and in the coolstoves *Kalmia latifolia*, a poisonous American plant, of which more may be said on a future occasion.

In the drug market large quantities of aloes have been offered during the past month, chiefly the Barbadoes and Curaçao kinds, the latter a variety we have not often noticed in retail commerce. It has much the appearance of Barbadoes aloes, but is rather more glossy and has a different and somewhat sulphureous odour. Sarsaparilla also has appeared in very large quantities. Among recent importations we have noticed Carnauba wax, obtained from the leaves of *Corypha cerifera*, Arr.; Cocum butter, a concrete oil from the seeds of *Garcinia purpurea*, Roxb., official in the Indian Pharmacopœia and used as a basis for ointments; Ceylon cardamoms, a long grey-tinted variety; China cantharides (*Mylabris Cichorii* and *M. phalerata*), which are said to contain more cantharidin than the Spanish fly; guarana; Chinese galls; eucalyptus oil; and gum acaroides, a resin which does not seem to have been turned to as much account as it is capable of. It is the product of one of the grass-trees of Australia and contains a quantity of cinnamic acid and an oil which has the odour of hyacinths, probably styrol. Japanese aconite has also been offered in larger quantities. A curious specimen of balsam of tolu, which is evidently a fictitious article, has lately come under our notice. It contains no crystals of cinnamic acid, dissolves in benzol and bisulphide of carbon, also in alcohol by the aid of heat, a portion separating on cooling. It has an odour like that of boiling syrup or molasses and an extremely tenacious consistence. It is at present undergoing further investigation.

In a previous article we referred to some observations made by Mr. Wanklyn in regard to Taunus water, and showed that his statements were based upon erroneous conclusions, arising from an imperfect comprehension of chemical physiology. That is to say, he argued upon the gratuitous assumption that carbonate of lime taken into the system is assimilated as such, and gives rise to various complaints, whereas the mass of existing evidence goes to show that this is by no means the case, and that hard waters are, speaking generally, productive of good to the human economy by strengthening bones and giving rigidity to their structure.

In his letter in the *Medical Times and Gazette* of January 20th, Mr. Wanklyn wrote "according to my knowledge, such an enormous quantity of carbonate of lime in a drinking water is not only an inorganic impurity, but a very dangerous and deleterious impurity," and again, "Certainly no chemist would dare to recommend the use of such a water for a population." Further, Mr. Wanklyn related that he was asked to express an opinion upon a similar water quite recently, and he unhesitatingly condemned it; he says "I should like very much to submit that opinion to you and your readers." Now in reply to Mr. Wanklyn, a letter was published by Mr. G. A. Ledeboer in the same journal for February 10th, in which certain facts are stated, to the effect that a number of gentlemen, well known in medical science, have prescribed Taunus water, and have also pronounced it not only "wholesome, but peculiarly beneficial in cases of indigestion, acidity, etc." But these facts fade away under the superior light of an editorial note, which, to quote, is as follows:—"Mr. Wanklyn stated certain facts; in opposition, Mr. Ledeboer states certain opinions; but that is all." With the last sentence we have nothing to do, it is beyond us; but we would submit that the editorial note in question would have been more correct had the statement of facts been credited to Mr. Ledeboer and that of opinion to Mr. Wanklyn.

Adopting the tone of Mr. Wanklyn's letter, it might be urged that distilled water constitutes that which it is best to drink; but, however true this may be theoretically, the chemist who would recommend it in preference to Taunus water would certainly be as bold as he who may dare to recommend Taunus water, and we believe some chemists there are who dare do even that.

The subject demands attention, from the fact that Mr. Wanklyn does not start on a philosophical basis with a standard water, and then proceed to go through the various declensions of danger, but he fixes on a water which has gained considerable favour as a beverage, and which represents moneyed interests. Such a proceeding is objectionable on more than one ground and is not above suspicion while Apollinaris water escapes free.

We leave this matter, to note several other subjects of more or less passing interest. In an interesting paper communicated on February 14th to the Society of Arts, Professor Barff has proposed to substitute pigments made with white lead by others having sulphide of zinc as their basis. Beyond the fact that white lead paints turn black when exposed to air containing even traces of sulphuretted hydrogen, they also give rise to a number of cases of lead poisoning, though it must be admitted that these generally ensue from neglect on the part of workmen, who too often are content to take their meals with hands sullied by such paints. White lead pigments moreover do not last well, although they are esteemed when recently prepared on account of their opacity, yet, on keeping, this opacity is lost, owing to the saponification of the oil used in the mixing by the oxide of lead, which produces "lead plaster," or oleate of lead, a body of more than ordinary transparent nature. The pigment recommended by Professor Barff is the invention of Mr. Griffiths, of the Silicate Paint Company, Liverpool, and is prepared as follows:—A solution of sulphate of zinc contained in a vat is precipitated by one of sulphide of sodium, and into the mixture thus resulting there is charged a quantity of sulphate of barium and a little magnesia. The mixed precipitate is isolated, washed, dried, and then roasted, giving a product of an excellent white colour, which mixes well with oils and has good body. The whiteness is due to the admixture of the baric sulphate, while the softness is derived from the magnesia.

The most important part of Professor Barff's paper has yet to be noticed. After describing the chemistry of the processes by which iron articles rust in a damp atmosphere, viz., by the formation first of ferrous oxide, and the peroxidation of this to ferric oxide, which readily crumbles off, he referred to the other oxide of iron known as "magnetic oxide," and formularized Fe_3O_4. This oxide results when steam is conveyed over iron heated to a considerable temperature; the steam is decomposed, the oxygen being fixed by combination with the iron, and the hydrogen escapes. Professor Barff was the first to observe that the magnetic oxide thus produced upon iron goods has a coherent state, and does not chip off, while it has been long known that it is capable of withstanding the action of air and water, and is not even altered by a damp atmosphere impregnated with acid fumes. He proposes to apply this steam process to all articles made of iron which are not too large to manipulate. Under this heading would be included cooking utensils, lamp posts, gratings, gas and water pipes, and so forth, and a most important direction in which this invention could probably bef applied would be in regard to the iron tackle o yachts and other vessels.

The only thing required is to place the articles in ovens or furnaces heated to 500° F. or 1000° F., according to the density and extent of magnetic oxide coating required, and then to blow through the chamber a current of steam for some five, six, or seven hours. It may be fairly expected that important results will follow from Professor Barff's process, for not only will goods made of iron be thus enabled to withstand the wear and tear of atmospheric influences, but it will probably prove possible to use iron where before it has not been possible, viz., for statuary and architectural work.

Leaving the subject of applied science, there are several matters worthy of note in more abstract scientific directions.

M. Albertoni, of Sienna, has published the results he has obtained in a study of the effects produced by the transfusion of blood, and he finds that transfused blood derived from the same species serves to form living tissue, and constitutes, in fact, a true blood-graft. But when the transfused blood comes from a different species this is not the case; the corpuscles dissolve and their colouring matter is eliminated in the urine, while the stroma partially coagulates and stops up the capillaries, obliterating them and causing not only grave accidents, but sometimes death.

While speaking of blood, we would note a preparation recently inroduced under the name of "Serum Sanguinis Exsiccatum." It is obtained from blood by allowing it to stand, removing the clot which forms in the meantime, and evaporating the resulting serum in chambers warmed by a gentle heat; in fact the preparation is ordinary blood albumen in a powdered state. Ten ounces are stated to yield about one ounce of the preparation, which is the ordinary yield of albumen obtained by the makers from blood; one gallon of serum yielding about 1lb. 1oz. of albumen dry at 100° C. The preparation to which we refer is soluble in water and is recommended not only as a blood medicine, but as an article of diet, to be used in the preparation of soups, gravies, and so forth. Whatever value it may possess for these purposes has not been so thoroughly established as is desirable, and in any case the greatest care should be observed in the making of the preparation, to ensure that the blood used in the process not only comes from healthy animals but is moreover perfectly fresh.

The importance of this matter comes out strongly if we place any faith in a theory of typhoid fever lately propounded by Mr. W. Stewart, L.R.C.P., etc.* This gentleman has endeavoured to fix upon the actual disease-bearing substance essential to typhoid fever, and he quotes a number of cases in his paper that lend weight to his hypothesis, which also derives support from some experiments of M. V. Feltz. Mr. Stewart believes that albumen in a state of putrefaction contains and carries the matter which by its reception into the system produces the disease of which we are treating. The albumen may originally have been derived from the blood of slaughter houses, or from the liquid evacuations in cases of diarrhœa. In these evacuations it must be remembered that much albumen is held in solution and is referable undoubtedly to the serum of blood. The experiments of M. V. Feltz consisted in injecting dried putrid blood mixed as a powder with water into the crural veins of dogs, when in all instances many symptoms were developed that are characteristic of typhoid fever. Beyond this, the effects strongly remind of the ordinary forms of this disease. Whether typhoid fever is to be referred to putrid albumen or not, it is at any rate more reasonable to follow up such a possibility and to investigate in similar directions, than it is to idly imagine the existence of a "contagium vivum" which defies isolation and which is not amenable to the laws of chemical science. It is important above all things, to bear in mind that by the expression "health" we mean the result of those processes of a chemical and physical nature which in their equilibrium allow animal life not only to exist but to exist free from disturbing influences. In their turn these influences are likewise of a chemical or physical nature, apart from the first cause, and in this sense they constitute the declensions of health.

It is absolutely impossible to describe those conditions which by their existence are capable of causing an outbreak, say of scarlet fever, and all we know of the disease is this, that the contagious matter is contained in the dry skin of those who suffer from it. But here is a tangibility, and with it we can at least appreciate its power to spread the disease. The matter is an infectant; it is matter in a state of change; and here it is that the physician must apply his knowledge with the view of extinguishing the disease, and he can only do this by bringing about a change in the actual state of the infectious matter. Those agents which can thus be used are truly disinfectants, and among these Dr. Day, of Geelong, would give to peroxide of hydrogen a foremost place. Between April, 1873, and the same month of 1875 he treated 51 cases of scarlet fever by anointing the bodies of his patients with lard containing peroxide of hydrogen, and in some cases he caused his patients to gargle a very dilute solution of the same reagent. Under this treatment there was extension of the disease only in four houses and there were no deaths. Subsequently Dr. Day treated 64 other cases, and out of these

* *British Medical Journal*, March 10, 1877.

only six proved fatal, while there was an extension of the disease only in three cases. Although we cannot accurately define the action of the peroxide of hydrogen in destroying the contagious nature of the matter thrown off from the skin in cases of scarlet fever, we can at least comprehend its possible mode of action. Just as the decomposition of potassic chlorate takes place on heating, the heat set free in the breaking up of one molecule into potassic chloride and free oxygen being sufficient to cause the decomposition of another, so we can also imagine organic matter in a state of change to exert a corresponding influence upon previously wholesome matter. If, however, the first molecule, while in the act of changing, could be so influenced by applied outside agencies, as for instance artificial cooling, as to reduce the temperature, the residual molecules of potassic chlorate would be rendered incapable of change under the circumstances. So also we can affect diseased matter that it is rendered powerless to infect, and among such agents peroxide of hydrogen takes its place by reason of its strong oxidizing character.

This direction of medical science is sacrificed in great measure at the present time on the altar of biology, which, however, has its proper function. While, as Dr. Moxon pointed out in his Hunterian oration, biology directs its aim to the ascertaining the circumstances and conditions upon which life begins, continues and flourishes, it should be the object of the physician to begin at the other end, and learn how to obviate those evils which result from the wear and tear to which life is subject, and from those disturbances of equilibrium between matter and force which bring about disease.

PARIS STATISTICS OF THERAPEUTIC AGENTS.*

In the *Archives Générales* for January and February are two very interesting papers, the joint production of Professors Lasègue and Regnauld (the Director of the Pharmacie Centrale), bearing the title "La Thérapeutique jugée par les Chiffres." The figures here referred to are not derived from the consideration of the effects produced by the various therapeutical agents, but from the amount of these supplied by the Pharmacie Centrale to the various hospitals and charitable institutions under the governance of the Assistance Publique. These exhibit some curious variations and oscillations in the employment of various medicinal substances, which may serve as an indication of the amount of favour these have enjoyed or continue to enjoy.

The "Pharmacie Centrale des Hôpitaux et Hospices Civils de Paris," the authors of the paper observe, is an establishment positively *unique* in the world, wherein is centralized the preparation, the purchase, and the distribution, *without exception*, of all the medicinal substances employed in the hospital establishments of the metropolis. First founded in 1794, its definite organization was due to Soubeiran; and subsequent improvements have constituted it an establishment of exceptional importance, where all the pharmaceutical preparations are made, and simple drugs and chemical products are submitted to the most rigorous examination by a large committee chosen from among highly competent persons. A strict account is kept of all medicinal substances which enter or are sent out of the establishment, and the tables exhibiting these are the sources whence the material for this paper has been derived. Unfortunately, it is not possible to exhibit the revolutions that medical practice has undergone in this respect during the early years of the existence of the Pharmacie Centrale, as the books of the establishment after they had served their immediate purposes of control were successively destroyed. So that the tabular statements for the last twenty years only are available, with the single exception of those relating to leeches, which go back uninterruptedly to the year 1820.

To instance the increase in consumption of some medicinal substances which have only come into use in recent times, it is stated that while 195 kilogrammes of *sulphuric ether* were consumed in 1855, these increased to 614 kilo. in 1875; and *chloroform* rose from 141 kilo. to 308 kilo. in the same period. *Chloral* first appears as 5 kilo. in 1869, and in 1875 had increased to 360 kilo. *Iodoform*, first entered at ½ kilo. in 1859, reached 28 kilo. in 1875. The *bromide of potassium*, which figures only at 3¼ kilo. in 1855, and in 1863 had only reached 7¾ kilo., then succeeded in establishing itself in professional favour, and rose progressively from 22 kilo. in 1864 to 731 kilo. in 1875. The consumption of *opium* has undergone little change, this having been 148 kilo. in 1855, and 151 kilo. in 1875; but *morphia*, as would be expected from the generalization of hypodermic injections, has made an immense stride from ¼ kilo. to 10⅓ kilo. The *sulphate of atropia*, from 9 grammes in 1855, rose to 1 kilo. in 1873, falling to 780 grammes in 1875. The quantity of leaves of *hyoscyamus* amounted to 15 kilo. in 1855, and after undergoing great variations in the interval, was 90 kilo. in 1875. Passing over some observations on emetic and antispasmodic substances, we come to *alcohol*, which has assumed a "colossal" rate of increase: in 1855 there were 1270 litres consumed, and 37,578 litres in 1875. Brandy, rum, and red wine have manifested the same progression, while white wine has greatly decreased in consumption, especially during the last two years. In curious contrast with this increase in the consumption of alcoholic liquids is the utter decline in the employment of *leeches*. Of this an account has been preserved since 1820. Between that year and 1824 the mean annual number was 183,000, and this rose during 1824-30 to 508,000. The hirudomania attained its apogee during 1830-37, when the mean annual number of 828,000 was reached; it amounted on three occasions to more than 1,000,000 per annum. From 1837 the numbers began to decline, moderately at first, but since 1863 precipitately—so that in 1874 only 49,000 were employed. The expenses have followed the same course, these amounting on three occasions to between 1830-42 to 100,000 fr., being nearly equal to 200,000 fr. at the present time. In 1875 they fell to 1600 fr., which would not be more than 1000 fr. in 1840, *i.e.*, a sum two hundred times less. The amount of *sulphate of quinine* consumed has about doubled, 24,525 grammes having been employed in 1855, and 53,734 in 1875.

Professors Lasègue and Regnauld terminate their first paper with the following observations:—

"The medicinal substances which we have now passed under review act, for the most part, as modifiers of the nervous system, with various titles, and under sufficiently different rubrics. Without attaching to the gross figures more importance than should belong to them, we may be allowed perhaps to hazard some deductions. Medical curiosity has, especially within the last ten years, undergone a change in its direction, abandoning local inflammatory affections, and even general diseases of the zymotic type, to occupy itself with nervous affections. In this respect science has made enormous progress. New species have been discovered, and confused agglomerations have been subjected to skilful analysis. In this work, so fertile in a pathological point of view, therapeutics as yet has not found its place. Medicinal indications are neither augmented nor perfected, and we witness the spectacle so often renewed of a pathology without a parallel therapeutics. Nevertheless, progress has been made by the introduction into the materia medica of new remedies directed almost exclusively to sensibility, in order to

* From the *Medical Times and Gazette*, February 3, and March 10, 1877.

diminish or annul it. It is thus that chloral has followed, as we have seen, an enormously increasing march, while neither opium nor other anæsthetics have diminished in amount. When we consider, summing up the figures, that there are consumed annually in the Paris hospital establishments 350 kilo. of chloral, 250 of iodoform, 300 of chloroform, 250 of opium, 10 of morphia, and 750 of bromide of potassium, we are struck by the immense favour which these agents, all more or less anæsthetic, enjoy. On the other hand, the stimulants of sensibility, and especially those of motion, have either kept at uniform figures or have undergone a notable decrease. The more that disturbances in locomotion have found their explanation in definite lesions of the the nervous centres, the less has the efficacy of *tetanisantes* substances been relied upon. [A table is given showing the stationary condition or decreased employment of nux vomica, St. Ignatius' bean, strychnia, brucine, ergot, etc.] Antispasmodics lend themselves little to statistics. Administered without conviction, and destined to produce only doubtful effects and at long intervals, they are usually but an expression which fills up the vacuities of treatment. Perhaps the time is approaching when, in place of addressing ourselves to consequences, we shall endeavour to ascend to causes. The therapeutics of the nervous system will then essentially consist of medicinal substances intended to modify the general or local circulation, and to struggle with reflex affections at their point of origin. Then, with the exception of anæsthetics, which respond to an immediate necessity, the nervine remedies of heretofore will become mere accessories of a second order."

In the second paper, commencing with the subject of *purgatives*, the authors observe that just as in a former period blood-letting preceded or accompanied all other important means of treatment, this position has been assigned more or less completely in more recent times to purgatives. In the hospitals, artificial compounds of soda, potass, or magnesia replace the natural purgative waters, the use of which is so much on the increase in private life. This is to be regretted, as it leads to the presenting the solutions of these salts in much too concentrated doses at intervals, while in smaller quantities they might be advantageously given more continuously. Of these *saline* purgatives, carbonate of magnesia and the sulphates of magnesia and soda have held the first places since 1855, a mean annual quantity of 3500 kilo. being consumed. The mild *vegetable* purgatives, with the exception of castor oil and senna in the children's hospitals, are not consumed in any important quantities. In fact, vegetable medicinal substances are fast losing their credit in France; and the tisanes, once thought of such importance, are left to the fancies of the patients themselves. Castor oil is, however, continually increasing in consumption. In 1875 the quantity used (3389 kilo.) nearly equalled the entire quantity (3675 kilo.) of all the saline purgatives put together. Taking the doses of both these classes at a mean of twenty grammes, there were administered during 1875 as many as 400,000 purgatives in the different hospital establishments, without counting other laxatives of lesser power. *Drastic purgatives* exhibit differences in the amounts consumed which are not easily accounted for. Aloes, however, has constantly increased in favour, rising from 10 kilo. in 1855 to 23 kilo. in 1875. Croton oil and gamboge have also quadrupled in quantity during the same period; while colocynth, never having attained more than 1 kilo. per annum, retired altogether in 1875. Jalap, from $30\frac{1}{2}$ kilo. in 1860, fell to 7 kilo. in 1875; and scammony, from $6\frac{1}{2}$ kilo. in 1855, rose to $11\frac{1}{2}$ kilo. in 1870, to fall to $8\frac{3}{4}$ kilo. in 1875.

Iodine.—As a cutaneous derivative, this is tending to replace all other revulsives, issues and permanent blisters being now well-nigh abandoned in its favour. The great abuse of the employment of issues has, however, led to a too favourable appreciation of iodine as an external application in phthisis and in affections of the joints. The tincture of iodine has increased during the twenty years from 48 kilo. to 150 kilo. The iodide of potassium, from 248 kilo. in 1855, has amounted to up 558 kilo. in 1875; but as the doses have been largely increased within the last ten years, the increase of a medicine of such approved value has not been so great as might have been expected.

Mercury.—The annual mean of this has varied from 200 kilo. to 250 kilo., a maximum of 331 kilo. having been attained in 1870, and a minimum of 178 kilo. in 1874. The quantity of mercurial ointments applied is slowly decreasing, while that of corrosive sublimate has enormously augmented of late, chiefly owing to its greatly increased employment in baths. From 1855 to 1871 the quantity varied from 30 kilo. to 60 kilo., but in 1872 suddenly rose to $106\frac{1}{2}$ kilo., and amounted to $135\frac{1}{2}$ kilo. in 1873, $141\frac{1}{2}$ kilo. in 1874, and $102\frac{1}{2}$ kilo. in 1875. The consumption of calomel has varied but little, having been from 40 to 50 kilo. per annum. The iodides have been nearly stationary.

Chlorate of Potash.—This salt, long neglected, was first used as a remedy in mercurial stomatitis. Its sphere since then has been continually augmented until (by an exaggeration that is to be regretted) it has been placed at the head of the means of combating stomatites and anginas of every description. From 39 kilo. in 1855, it rose in quantity to 419 kilo., and in 1876 even attained a maximum of 502 kilo.

Cod-liver oil is another remedy that has increased uninterruptedly from the important amount of 9576 kilo. in 1855, to 18,571 kilo. in 1875. The *phosphate of lime*, which is used for analogous purposes, has oscillated between 100 and 300 kilo.

Iron.—Of the preparations of this metal used in the Paris hospitals, reduced iron and the subcarbonate, while standing at the same figure (76 kilo.) during 1870–75, have reached it by inverse ratios, the former increasing from 54 kilo. in 1855–60, and the latter decreasing from 108 kilo. The carbonate has risen from 15 to 30 kilo. and the lactate has descended from 3 kilo. to 1 kilo. The protoiodide is the only preparation that has made a marked increase (from 22 to 93 kilo.), and that is rather due to the iodine than the iron which it contains. In old pharmacopœias the perchloride of iron holds an important place; but it gradually lost its reputation as a tonic. But its styptic and coagulating power has conferred upon it in recent times an importance which is on the increase. The amount used increased from $62\frac{1}{2}$ grammes in 1855-1860, to 155 grammes in 1865-70, and to 129 grammes in 1870–75.

Arsenic.—The quantity of this used in Fowler's solution has progressively increased from 1 kilo. in 1855 to 13 kilo. in 1875; while that of granules of arsenious acid has increased from $\frac{1}{3}$ kilo. in 1867 (when it first appeared) to $10\frac{1}{2}$ kilo. in 1875. Arseniate of soda has been little employed, except in the form of baths. *Alkaline* remedies have continued well-nigh stationary during the last twenty years.

The confidence in the efficacy of *vegetable bitters* during this period has continued to increase. They were held in high esteem by physicians at the end of the eighteenth century, and, although their employment declined during the prevalence of Broussaism, it never ceased, and has naturally increased since tonic and corroborant medicines have again come to the foreground, and have attained the somewhat exaggerated proportions of a victorious reaction. Between 1855 and 1875 the quantity of hops has risen from 1290 to 3794 kilo., that of gentian from 524 to 1518 kilo., of quassia from 31 to to 271 kilo., and of calumba from 12 to 44 kilo. The mean annual consumption of chicory has been 500 kilo., of camomile 200 kilo., and of absinthium 400 kilo. The progress of *pepsine* has been remarkable. First introduced into the hospitals in 1860, when $\frac{1}{2}$ kilo. was consumed, it has oscillated during the years 1873-75 between 28 and 44 kilo.

"Have we then found that *rara avis*, a remedy introduced into therapeutics without empiricism, taking its place by virtue of rational principles, and passing without transition from the laboratory of the physiologist to the bedside of the patient, there to gain its domicile? For our part, our personal trials of it, and the almost insurmountable difficulties of clinical observation, leave in our mind so much indecision that we cannot help regarding pepsine as a matter still in process of experiment, the harmlessness of which is not its least merit."

The *vegetable astringents* present great stability, 40 kilo. of tannin per annum being almost regularly consumed, as also 88 kilo. of oak bark, 300 kilo. of rhatany, and 20 kilo. of catechu. Of bismuth, which may be associated with these, the annual mean has been 350 kilo., the minimum not sinking below 250 kilo., and the maximum not rising above 450 kilo., even during epidemics of cholera, when it is resorted to even for slight diarrhœa. The years of the siege of Paris, 1870 and 1871, however, present a curious anomaly, the consumption of bismuth amounting to 520 kilo. during the first of these, and to 660 kilo. during the second. Of the *sulphurets*, the use of the monosulphuret of sodium, principally employed as a substitute for sulphuretted mineral waters, has increased from 1300 grammes in 1855, to 4800 grammes in 1875; and that of the polysulphuret, used for sulphur baths, has increased from an annual mean of 9352 kilo. to 19,300 kilo. Sublimated sulphur, chiefly used for the itch, has not varied in quantiiy during twenty years, the consumption being 1000 kilo. per annum. Glancing cursorily at other articles of the materia medica, it is found that the quantity of *glycerine* employed increased from 200 kilo. in 1855, to 6000 kilo. in 1875; and the progress of *collodoin* has been still more rapid, viz., from 13 kilo. in 1855, to 150 kilo. in 1875. *Silicate of potash*, which first appears in 1865 as 10 kilo., reached in 1875 nearly 3000 kilo. *Carbolic acid* rose from 162 grammes in 1862, to 306 kilo. in 1873, 278½ kilo. in 1874, and 221 kilo. in 1875. The great increase of *tœniafuges* corroborates the fact clinically observed for some time past, that the prevalence of tænia has greatly increased in Paris. Comparing the five years which preceded and the five years which followed 1870, the consumption of *kousso* increased from 4 to 5 kilo.; of *pumpkin seeds* from 3 to 5½ kilo.; of *pomegranate bark* from 13 to 14 kilo.; and of *male fern* from 5 to 12 kilo. From the doses having continued much the same, it may be concluded that the number of patients treated for tænia in the Paris hospitals has doubled within the last five or six years. Other anthelmintics employed for the treatment of ascarides, lumbrici, etc., have continued stationary in the amounts consumed.

THE QUALITATIVE EXAMINATION OF CINCHONA AND OPIUM.

In the "Guide pratique pour servir à l'examen des caractères physiques, organoleptiques, et chimiques des preparations pharmaceutiques," published by Messrs. Lepage and Patrouillard, the authors give the following processes:—

Cinchona.—Take a fragment from several barks in the same bundle and reduce to a fine powder; suspend 1 gram of the powder in 10 grams of distilled water containing 1 gram of dilute sulphuric acid, and leave them in contact two or three hours, agitating frequently. At the end of this time add 70 grams of distilled water and leave in contact several hours more, still taking care to agitate the mixture frequently. Then allow it to deposit, and afterwards filter. If the cinchona be of good quality, solution of the double iodide of cadmium and potassium, prepared by dissolving 2·80 grams of iodide of cadmium and 7·50 grams of iodide of potassium in 50 grams of distilled water, when poured in slight excess into this liquid, should produce at once an abundant turbidity, resulting after some hours in a voluminous precipitate. If the bark contain no more than 10 or 12 parts of alkaloid per 1000 the reagent does not give rise to any turbidity, or at most to a slight opacity. The yellow, red and grey barks may be examined in this manner.

Opium.—Reduce 0·10 gram to powder in a glass mortar and suspend the powder in 25 grams of distilled water; leave the mixture in contact during half an hour, agitating occasionally, and then filter. Take two-thirds of this liquor, which should possess a markedly bitter taste, and pour into it some drops of solution of iodide of cadmium and potassium. If the opium be of good quality an abundant turbidity is produced to which rapidly succeeds a flocculent precipitate; whilst if it contain not more than 4 or 5 per cent. of alkaloid or less, at the most a slight turbidity will be produced. The one-third part of the solution that is reserved, when tested with very dilute perchloride of iron ought to acquire a decided red colour, which is the reaction characteristic of meconic acid.

THE DISTRIBUTION OF CARDIAC POISONS IN THE VEGETABLE KINGDOM.*

BY PROFESSOR T. HUSEMANN.

The number of plants which have up to the present time been recognized as cardiac poisons is comparatively small and confined to but few natural families; and the number of pure proximate principles obtainable from these plants is nearly equal to the number of plants themselves, as the presence of several pinciples in one plant appears to be counterbalanced by their absence in others. It is a remarkable fact that all firmly established active principles which affect the heart's action, like digitalis, have been found to be glucosides, with the sole apparent exception of that from oleander, which is said to contain an alkaloid as its active portion. But the chemical history of this plant is by no means fully studied, and it is quite likely that on further investigation the supposed alkaloid will resolve itself into a glucoside.† It is probable that most of these plants contain other proximate principles, acting upon the nervous system in one way or another, as for instance the glucoside digitonin, resembling in its action saponin, in *Digitalis*; or helleborin, resembling the hypnotic opium-alkaloids, in *Helleborus niger*, and *H. viridis*, etc. The only exception appears to be *Thevetia neriifolia*, which was recognized as a cardiac poison by Professor Husemann, and which appears to contain only a single glucoside.

We now turn to the consideration of the various natural families furnishing these poisons, begining with the dicotyledonous group. The majority of the latter are represented by a solitary genus, or even species, while only one family, the Apocynaceæ, furnishes several representatives. The importance of the latter family will justify us in placing it at the head, especially as it is highly probable that other members of it, as yet unstudied, will be found to possess similar properties. In the following notes only such points are mentioned or touched upon as are not generally found in the usual works on phytochemistry and pharmacodynamics, it being supposed that the latter works will be consulted for further information.

1. Apocynaceæ.

The oldest known cardiac poison belonging to this family is *Tanghinia venenifera*, Poiret (*T. Madagascariensis*, Pet. Th.; *Cerbera Tanghin*, Hooker), native of Madagascar and other islands of the east coast of Africa,

* Abstract of a paper in *Archiv der Pharmacie*, Nov., 1876.

† Schmiedeberg, in *Beitr. f. Anat. und Physiol.*, has indeed lately shown that oleander does not contain an alkaloid, but a glucoside, with cardiac effect.

the bitter seeds of which are employed—like Calabar beans—by many African tribes as *criteria culpæ* in ordeals. Their chemical investigation cannot be considered as terminated, since the crystalline substance obtained from them, and termed tanghicin, does not produce the characteristic effects of the seeds. The activity of the latter is, on the contrary, ascribed to a brown, sticky mass extracted from the seeds, and not entitled to be counted among proximate principles. Husemann. however, suspects that this crystalline tanghicin (of Henry and Ollivier) still partakes of the general properties of the seeds, since it causes intense vomiting in dogs, which is well known to be a main symptom of cardiac poisons. Whether tanghicin is a glucoside or not, is unknown; but the investigations of Kölliker and Pelikan (1850) prove, beyond doubt, that an alcoholic extract of tanghinia seeds is an active cardiac poison; and this alcoholic extract must necessarily contain tanghicin, which therefore was made to take part in the experiments of the last-mentioned physiologists. Should there be discovered in tanghinia a second substance affecting the cerebral functions, as it is made probably by the researches of Ollivier and Henry (who administered some of the above-mentioned brown mass to a guinea-pig, which fell asleep standing), the constituents of the plant would be analogous to various species of *Helleborus*.

Nearest related, botanically, to *Tanghinia venenifera*, is *Thevetia neriifolia*, Jussieu (*Cerbera Thevetia*, L.), native of the West Indies and South America; the *ahovai-tree* of the Antilles, which contains, especially in the fruit, the glucoside thevetin, first studied by Blass and demonstrated by Husemann to act upon the heart, as likewise does its derivative theveresin. Since the substance thevetin is also found in the bitter seeds of *Cerbera Odallam*, Ham., the Javanese Mangas (Manghas), or resin-tree, there can be no doubt that the latter apocynaceous plant is also a cardiac poison.

A fourth member of this group is the arrow-poison, *Iné*, *Onage*, or *Kombe*, which is used in a large portion of Africa in the killing of large game (elephants, etc.). Pelikan, in 1865, first proved this substance to belong to the cardiac poisons, and his statements were corroborated by the investigations of Fraser (1871), Polaillon and Carville (1872), and Valentin (1873). The source of the poison is a species of *Strophanthus*, either *S. hispidus*, according to Baillon, or a new species, *S. Kombi*, according to Oliver. Fraser claims to have isolated, from an alcoholic extract of the seeds, the active principle, which he called strophanthin, but he has not furnished data.

The fifth member of this group is the well-known oleander, *Nerium Oleander*, L., the chemical constituents of which have so far not yet been established with satisfactory exactness. Lukowsky reported the discovery in oleander of two alkaloids, oleandrin and pseudocurarin, but these were not obtained in a pure state, and require re-examination. It remains to be seen whether Lukowsky's oleandrin, described as a faintly yellow, resinous and very bitter body, is identical with the yellow acrid resin obtained by Pelikan (1866), and pronounced by him as the active cardiac principle of oleander, mixed, however, in the plant with substances which were said by him to interfere with its action. The possibility of the existence of alkaloids in oleander cannot be denied *à priori*, particularly as another nearly related plant, belonging to the same natural family, undoubtedly contains an alkaloid, namely, conessine or wrightine, in the bark and seeds of the East Indian *Wrightia antidysenterica*, R. Br., which Linné classified under the genus *Nerium* (as *N. antidysentericum*). The last-named plant, however, as has been shown by Husemann in 1865, does not contain a cardiac, but a cerebro-spinal poison.

The poisonous properties of *Wrightia dysenterica* show that in the search for other cardiac poisons among the Apocynaceæ we must not always expect to find them in the nearest congeners to plants already known to contain them. Botanical relationship alone does not decide, and in this family particularly especial care must be exercised, as it contains plants of widely varying poisonous characters. Besides the above-named *Wrightia*, this family includes a great number of topical plants, which contain an acrid, milky juice, and may be classed among topical poisons or drastic purgatives. Many species of *Rauwolfia*, *Echites*, and *Tabernæmontana* belong to this kind.

A few North American members of this family appear yet to deserve particular attention. *Apocynum cannabinum*, L., is considered as antihydropic, and is also used as an emetic. It is a favourite remedy of the eclectics, together with another species, *Apocynum androsæmifolium*, L., both of which are generally used in the form of resinoids. This so-called apocynin is said to be an excellent alterative aperient, possessing tonic and diuretic properties. It is quite possible that *Apocynum* may contain a cardiac poison, but on the other hand its effect may be attributed to a topically irritant constituent, as we find the statement that the milky juice is capable of blistering the skin, and that even the effluvia and evaporation of the plant causes swelling of the skin, which properties would make it appear to resemble the poison-sumac and manchineel tree.

Finally, there is to be mentioned one other plant, belonging to this family, namely, *Vinca minor*, L., or lesser periwinkle, which is regarded as an excellent diuretic in many parts of Germany, while in others it is esteemed as an effective remedy in dysentery. The possibility of the existence in this plant of a cardiac poison may also extend to other species of the same genus, for instance, *Vinca major*, L., which has been used in other countries for similar purposes.

2. Scrophulariaceæ.

This natural family is distinguished by the peculiarity that one and the same species contains quite a number of cardiac poisons as glucosides. This is foxglove, or *Digitalis purpurea*, L., with three glucosides producing cessation of heart's action in systole—which we denominate digitalin, digitalein, and digitoxin — together with a fourth, resembling saponin in its action, and a fifth (digitin) which is inert.

After the researches of Schmiedeberg had shown that the substance called digitalin did not altogether consist of cardiac poisons, we are enabled to understand the varying statements about the greater or lesser activity of the different species of digitalis. Since we have acquired a clearer knowledge, in general, of the chemical constituents of digitalis, and since we know that the substance digitoxin (the principal constituent of Nativelle's crystallized digitalin) acts with much greater energy than the two other glucosides, the question arises, whether the differences of effect, which season, place of growth, and quality of soil produce in digitalis,, is not owing to the excessive or defective production of one or another of these glucosides. Various analogies appear to corroborate this view; among others, the influence of sunlight and shadow, noticed by Stenhouse, upon the active constituents of Sarothamnus Scoparius, and the increased percentage of quinia in East Indian bark treated by manuring.

Among the plants which are nearest related to digitalis, we could scarcely name a single genus which might be suspected to contain a cardiac poison. The nearest approach to it is perhaps *Chelone glabra*, L., which we learn is used by the North American Indians as a tonic and anthelmintic; but it cannot be reckoned among the poisons. A very poisonous plant belonging to this family, and generally omitted in toxicological works, is *Franciscea uniflora*, Pohl.; but our accounts of this Brazilian plant are insufficient to decide whether it belongs to the agents of local or remote effect; it is considered as a hydragogue cathartic, abortive, and antisyphilitic, on account of which latter property it is named *Mercurio vegetal*.

(*To be continued.*)

The Pharmaceutical Journal.

SATURDAY, MARCH 31, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary,* 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

THE EXAMINED MEN ON THE REGISTER.

THE publication to day of the Registers of Pharmaceutical Chemists and Chemists and Druggists enables us to complete our annual review of the statistics of British pharmacy, begun on p. 655, by showing the progressive increase in the number of examined men on the Register, as compared with that of the previous year. It will be remembered that last month the Registrar reported that at the end of the year there were 2321 registered Pharmaceutical Chemists. Of these 1381, or 55·2 per cent., are now shown to be so registered by virtue of having passed the Major examination, against 1248, or 53·4 per cent., in the previous year. The proportion which this number bears to the whole number of Chemists and Druggists is 9·72 per cent., against 9·40 per cent., in the previous year. Besides these 1281 Major men, 1918 persons who are registered as Chemists and Druggists have passed the Minor examination, making a gross total of 3199 examined men. These 1918 persons represent 14·55 per cent. of the whole number of registered Chemists and Druggists, and, added to the 9·72 per cent. who have passed the Major also, give a total of 24·27 per cent. of examined men now on the Register of Chemists and Druggists. Thrown into a tabular form the result is as follows:—

	Jan. 1, 1876.				Jan. 1, 1877.			
	Number.		Per cent.		Number.		Per cent.	
Pharmaceutical Chemists:—								
Examined . . .	1248	2335	9·40	17·59	1281	2821	9·72	17·59
Non-examined	1087		8·19		1040		7·87	
Chemists and Druggists (only) who have passed the Minor . . .		1775		16·22		1918		14·55
Remainder, including those who have passed the Modified . . .		9166		66·19		8939		67·86
Total		13,276		100·00		13,178		100·00

We avail ourselves of the opportunity of stating that in some of the issued copies of the Calendar, the publication of which we announced last week, there is an omission, through a printer's error, of the name of Mr. S. R. ATKINS, Market Place, Salisbury, from the list of Members of Council.

AMERICAN PHARMACY LAWS.

SCARECROWS, if not very elegant objects, are, at least in proper time and place, very useful ones. But we presume that when there is nothing further left for the birds to fly off with even the American farmer does not specially trouble himself to prolong their exhibition. Now it may be that once upon a time the British chemist and druggist could have been held up before his younger and more inexperienced United States brother as a warning against coquetting with legislators; but we were under the impression that that time had now passed by, and that the pharmacists in several States of the Union were now under the regulation, and congratulated themselves upon being so, of laws that more or less show signs of the influence of the English Pharmacy Acts. We are therefore surprised to read in *New Remedies* an editorial statement of opinion that the troubles of the British pharmacist,—from Medical Defence Associations, Public Analysts and Co-operative Stores,—are all due to the "class legislation" by which a monopoly was given to the pharmacist in return for restrictions placed round the sale of poisons and the dispensing of medicines, together with the expression of a hope that United States pharmacists, having escaped these dilemmas, will have the wisdom to avoid the cause. Since we are not unfrequently asked for information as to the conditions under which pharmacy is practised in the United States, we propose to illustrate this alleged avoidance of "class legislation," and at the same time to serve a useful purpose, by quoting a few details from the United States journals and reports for the last eight or nine years.

At the time of the passing of the English Pharmacy Act, in 1868, there were only four Pharmacy Acts in existence in the States, one for New York City, a second for Lycoming county, Pennsylvania, a third for the State of Georgia, and a fourth for Alabama. The first of these was never enforced; under the second a licence to practise pharmacy was sold by the State for a sum of money; only five persons in a population of five million chose to conform with the provisions of the third; whilst the fourth was not rediscovered until 1874. In 1869, the "urgent necessity" for legislation was recognized, and a series of resolutions was passed by the American Pharmaceutical Association and forwarded with a draft Bill to the speakers of the different Houses of Legislature.

The first result of this movement was that in March, 1870, a law was passed in Rhode Island, based upon these resolutions, and establishing an examining board to be *appointed by the Governor*, and confining the dispensing of medicines and poisons (1) to graduates in pharmacy at some recognized college, (2) to "practising pharmacists" in business at the time of the passing of the Act, and (3) to "practising assistants" who had served an apprenticeship of four years and passed an examination by the board. Appended was a schedule of poisons which were not to be sold without labelling and registration, and this provision applied to patent medicines composed wholly or in part of such poisons. In 1871 some modifications were introduced into this Rhode Island Act, one being the alteration of the term of apprenticeship to three years, another compelling persons who where in business at the passing of the Act to present themselves for examination.

In 1870, too, a law was passed for the city of Baltimore, providing that persons engaging in the business of dispensing or selling medicines in that city should be examined by a board of three examiners to be selected biennially by the Governor of the State of Maryland from ten pharmacists nominated by the Maryland College of Pharmacy. Poisons were not specially referred to. In 1872 this Act was amended so as to require also the registration of managing assistants and the exhibition of the words "Registered Pharmacist" before the pharmacy; a provision was also included that only such diplomas of colleges of pharmacy should be recognized as were based upon a four years' apprenticeship. Last year, however, the restriction was removed from the selling of "patent medicines," of all non-poisonous drugs, and of all compounds in original packages or bottles.

In 1871, a Bill was introduced into the New York legislature professedly to protect the citizens of that city (the home of our contemporary, *New Remedies*) from the "murderous drug clerks;" and notwithstanding the opposition of the principal pharmacists, principally on the ground that the appointment of the examining board was vested in a political officer, it became law. In the next session, however, the New York druggists succeeded in getting this obnoxious provision repealed and the appointment of the examining board was vested in the New York College of Pharmacy. Under this Act, all persons carrying on business in the city of New York, or acting as dispensing assistants, including those in business before the date of its passing, must satisfy the Board as to their competency.

In 1871 a Poisons Act *pur et simple* was passed for Pennsylvania.

In 1872 the California Legislature passed an Act regulating the practice of pharmacy in the city of San Francisco. The Act was based upon the modified New York Act, and the appointment of examiners was vested in the California Pharmaceutical Society. With a few alterations this law was last year extended to the county of San Fancisco.

The same year an Act was passed for Philadelphia, providing for the registration of all pharmacists in business in the city at the time, requiring the registration of all pharmacists and managers entering the business afterwards, but excepting graduates of recognized colleges of pharmacy. It prohibits any person who has not served two years' apprenticeship from dispensing medicines, except under the immediate supervision of a qualified person. In this case, however, notwithstanding strong opposition, the appointment of examiners was vested in the mayor of the city.

In 1873 an Act closely resembling the Philadelphia Act was passed for Ohio, to apply to cities having not less than 175,000 inhabitants.

In 1874 a similar law was passed in Kentucky, applying to towns with more than 5000 inhabitants; but here the Governor of the State, in whom the appointment of examiners is vested, is compelled to select four out of seven of them from the members of the Louisville College of Pharmacy.

St. Louis, Missouri, also obtained a similar law during 1874, the examiners to be appointed by the local college.

New Hampshire was the next to obtain a Pharmacy Act, passed in 1875, and applicable to the whole State. It provided that all persons conducting pharmacies either for themselves or others, except those who had been doing so six months before the date of its passing, should be examined by a board appointed by the Governor of the State.

Last year the pharmacists in South Carolina were admitted to a share in the application of the law to which reference has before been made, the administration of which had previously been entrusted to the medical colleges.

In addition to the foregoing we learn from the current number of the *American Journal of Pharmacy* that a pharmacy law for Maine has been recently passed and received the sanction of the Governor on the 9th ult. According to its provisions three suitable persons are to be appointed by the Governor as "Commissioners of Pharmacy," whose duty it will be to examine every applicant desirous of engaging in the business of an apothecary, and it will be incumbent upon every applicant to have been engaged three years in a store where prescriptions are compounded, or to have graduated in some regularly established medical college or school of pharmacy, and to prove his competence for the business.

The above is possibly not a complete list of all the Pharmacy Acts that have been passed in the United States since 1868, but it is sufficient to demonstrate the limited ground for congratulation—if indeed it be a subject for congratulation—our contemporary has in the freedom of American pharmacists from legislative bonds. But before leaving the subject we may remark that, having to submit to legislative control, it is some satisfaction that its application is entrusted to ourselves, and that the appointment of our examiners is not committed to a political officer with the consequent danger—which has before now been very present to the minds of our American brethren—that he will exercise his trust to secure party objects. On the other hand it is worthy of notice that in the majority of the Acts cited a poison schedule is either absent or plays a secondary part, the restrictions applying to the entire practice of pharmacy, whether by an employer or assistant.

THE EVENING MEETING.

THE last Evening meeting of the Pharmaceutical Society for the present session will be held at 17, Bloomsbury Square, on Wednesday next, the 4th of April. A paper by Mr. B. S. PROCTOR, on "Medicine Measures" will be read. The chair will be taken at half-past eight o'clock.

SCHOOL OF PHARMACY STUDENTS' ASSOCIATION.

A MEETING of the above Association will be held at 17, Bloomsbury Square, on Thursday evening next, April 5th, at eight o'clock, when a paper will be read by Mr. G. W. BULLEN on "Starches."

THE PROSECUTIONS BY THE APOTHECARIES' COMPANY.

WE are informed that an application having been made by the Solicitor of the Chemists and Druggists' Trade Association to the Apothecaries' Company, that its authority may be withheld from further proceedings under the Apothecaries Act until the determination of the appeal to the Court of Queen's Bench in Mr. SHEPPERLEY's case, a reply has been received stating that the Apothecaries' Company will give no such undertaking.

THE AGAVE AMERICANA AS A RUBEFACIENT.

SOME time since we referred to the esteem in which the *Agave americana* is held by the Mexicans and the various uses it is put to by them, and mentioned that it had fallen to the lot of General SHERIDAN to confirm its antiscorbutic properties. It is now brought forward in France as a rubefacient, producing effects analogous to those following the application of mustard flour. In a communication to the Société d'Acclimatation M. DECROIX says that this result is obtained by cutting the agave leaves into small pieces, reducing them to a pulp without heat, and then applying the pulp to the skin. It is said to have been used successfully by the French chasseurs during their campaigns in Algeria, both on man and horse. Several attempts have been made to isolate the active principle, for which the name agavine is proposed, but hitherto without success.

RYDE, ISLE OF WIGHT.

At the invitation of the local secretary for Ryde to the chemists of the Isle of Wight, a third of their number dined at Wavell's Hotel, Ryde, on March 22nd, when it was resolved to form a local association in connection with the Birmingham Trade Association, and for such other purposes as may be hereafter resolved. Regret was expressed that, from the scattered position of the towns, measures of an educational character were impracticable. Mr. John Wavell was elected president, and Mr. H. H. Pollard treasurer and secretary, and a committee of chemists from the various towns in the Island was appointed to consider what other steps were desirable, and to report thereon. Many members of the trade were prevented, some by unforeseen circumstances, and some by their being alone, from attending, but five-sixths of the entire number in the Isle of Wight had expressed their concurrence in the project by letter.

MEETING OF CHEMISTS AND DRUGGISTS AT NOTTINGHAM.

A meeting of the chemists and druggists of this town, convened by the local secretary of the Chemists' Association, took place at the Flying Horse Hotel, on the 21st inst., to consider various matters of importance affecting the interests of the trade; Mr. W. H. Parker in the chair. The meeting was very numerously attended, nearly forty members being present. The principal topic of discussion was the recent prosecution of one of its members by the Nottingham Medical Defence Association. During the evening, a vote of thanks was unanimously accorded to the Trade Association at Birmingham for the energetic manner in which they had undertaken the defence of simple counter prescribing; and, at the suggestion of the Chairman, subscriptions and donations were solicited, which were generously and freely responded to by all present. After touching upon other subjects, the meeting terminated to the satisfaction of all assembled, and the company dispersed after having cordially thanked the Chairman for the able way in which he had conducted the business of the evening.

Proceedings of Scientific Societies.

SOCIETY OF ARTS.

Certain Relations between Plants and Insects.*

BY SIR JOHN LUBBOCK.

The Council of our Society have determined this session to have a certain number of evening lectures, and have done me the honour of asking me to deliver the first. Your Secretary has, moreover, suggested that I should take for my subject a continuation of the lecture which I delivered before the British Association at Belfast, and which I have since expanded into a little book, on the "Relations of Flowers and Insects," and especially on the fertilization of flowers by insects. It would, no doubt, have been easy to occupy not only a single evening, but even the whole time of the course, by descriptions of the various ingenious contrivances through which this is effected. I propose, however, on the present occasion, to ask you to look at the question from a somewhat different point of view, and have taken for my title, "Certain Relations between Plants and Insects." This will include not only the modes of attraction, but the means of defence, which have been elaborated by plants, and also the influence exercised by plants on insects.

Neither plants nor insects, indeed, would be what they are, but for the influence which each has exercised on the other. We know now, for instance, that certain plants produce no seeds at all unless visited by insects. Thus, in some of our colonies, the common red clover sets no seeds on account of the absence of humble bees; for the proboscis of the hive bee is not long enough to effect the object. According to Mr. Belt, the same is the case for the same reason in Nicaragua with the scarlet-runner.

But even in those cases in which it is not absolutely necessary, it is a great advantage that the flowers should be fertilized by pollen brought from a different plant, and, with this object in view, insects are tempted to visit flowers for the sake of the honey and pollen; while the colours and scents are useful in making the flowers more easy to find.

The real use of honey, indeed, now seems so obvious that it is remarkable to see the various theories which were entertained on the subject. Patrick Blair thought it absorbed the pollen, and then fertilized the ovary. Pontedera thought it kept the ovary in a moist condition. Linnæus confessed his inability to solve the question. Other botanists considered that it was useless material, thrown off in the process of growth. Krünitz even observed that in meadows much visited by bees the plants were more healthy, but the inference he drew was that the honey, unless removed, was very injurious, that the bees were of use in carrying it off. Sprengel was the first to show that the real office of the honey is to attract insects, but his views were far from meeting with general consent, and even so lately as 1833 were altogether rejected by Kurr, who came to the conclusion that the secretion of honey is the result of developmental energy, which afterwards concentrates itself on the ovary.

One reason why the earlier botanists missed the true explanation was, perhaps, that some plants secrete honey on other parts besides the flowers. Belt and Delpino have, I think, suggested the true function of these extra floral nectaries. The former of these excellent observers describes a South American species of acacia, which, if unprotected, is apt to be stripped of the leaves by a leaf-cutting ant, which uses the leaves, not directly for food, but, according to Mr. Belt, to grow mushrooms on. The acacia, however, bears hollow thorns, and each leaflet produces honey in a crate-formed gland at the base, and a small, sweet, pear-shaped body at the tip. In consequence, it is inhabited by myriads of a small ant, *Pseudomyrma bicolor*, which nests in the hollow thorns, and thus finds meat, drink, and lodging all provided for it. These ants are continually roaming over the plant, and constitute a most efficient body guard, not only driving off the leaf-cutting ants, but in Mr. Belt's opinion, rendering the leaves less liable to be eaten by herbivorous mammalia.

Delpino mentions that on one occasion he was gathering a flower of *Clerodendron fragrans*, when he was suddenly attacked by a whole army of small ants.

I am not aware that any of our English plants are protected in this manner from the browsing quadrupeds, but not the less do our ants perform for them a very similar function, by keeping down the number of small insects, which would otherwise rob them of their sap and strip them of their leaves.

Mr. Forel watched, from this point of view, a nest of *Formica pratensis*. He found that the ants brought in dead insects, small caterpillars, grasshoppers, cercopis, etc., at the rate of about 28 a minute, or more than 1600 in an hour. When it is considered that the ants work not only all day, but in warm weather often all night too, it is easy to see how important a function they fulfil in keeping down the number of small insects.

Some of the most mischievous, indeed—certain species, for instance, of aphis and coccus—have turned the tables on the plants, and converted the ants from enemies into friends, by themselves developing nectaries, and secreting honey, which the ants love. We have all seen the little brown garden ants, for instance, assiduously running up the stems of plants, to milk their curious little cattle. By this ingenious idea, not only do the aphides and cocci secure immunity from the attacks of the ants, but even turn them from foes into friends. They are subject to the attacks of a species of ichneumon, which lays its eggs in them, and Delpino has seen the ants watching over them with truly maternal vigilance, and driving off the ichneumons whenever they attempted to approach.

But though ants are in some respects very useful to plants, they are not wanted in the flowers. The great object is to secure cross fertilization; but for this purpose winged insects are almost necessary, because they fly readily from one plant to another, and generally confine themselves for a certain time to the same species. Creeping insects, on the other hand, naturally would pass from each floret to the next; and, as Mr. Darwin has shown in his last work, it is of little use to bring pollen from a different flower of the same plant; it must be from a different plant altogether. Moreover, when they quitted a plant they would naturally creep up another close by without any regard to species. Hence, even to small flowers (such as many cruciferæ, compositæ, saxifrages, etc.), which, as far as size is concerned, might well be fertilized by ants, the visits of flying insects are much more advantageous. Moreover, if larger flowers were visited by ants, not only would they deprive the flowers of their honey without fulfilling any useful function in return, but they would probably prevent the really useful visits of bees. If you touch an ant with a needle or a bristle, she is almost sure to seize it in her jaws, and if bees when visiting any particular plant were liable to have the delicate tip of their proboscis seized on by the horny jaws of an ant, we may be sure that such a species would soon cease to be visited.

On the other hand, we know how fond ants are of honey, and how zealously and unremittingly they search for food. How is it, then, that they do not anticipate the bees and secure the honey for themselves? Kerner has recently published a most interesting memoir on this subject, and pointed out a number of ingenious contrivances by which flowers protect themselves from the unwelcome visits of such intruders.

The most frequent are by the interposition of *chevaux de frise*, which ants cannot penetrate, glutinous parts which they cannot traverse, slippery slopes which they cannot climb, or barriers which close the way.

Firstly, then, as regard *chevaux de frise*.

* From the *Journal of the Society of Arts*, February 23, 1877.

In some respects they are the most effectual protection, since they exclude not only creeping insects, but also other creatures, such as slugs.

With this object it will be observed that the hairs which cover the stalks of so many herbs usually point downwards. A good example of this is afforded, for instance, by a plant allied to our common blue scabious, *Knautia dipsacifolia*. The heads of the common carline (*Carlina vulgaris*), again, present a sort of thicket, which must offer an impenetrable barrier to ants. Some species of plants are quite smooth, excepting just below the flowers. The common but beautiful cornflower (*Centauria cyanus*) is quite smooth, but the involucres forming the flower head are bordered with recurved teeth.

In this case neither the stem nor the leaves show a trace of such prickles. In this species the stigma projects about 1-5th inch above the flower, so that if ants could obtain access, they would steal the honey without fertilizing the flower; a flying insect, on the contrary, alighting on the flower, could scarcely fail to touch the stigma.

Kerner has called attention to very interesting illustration afforded by the *Polygonum amphibium*. The beautiful rosy flowers of this species are rich in nectar; the stamens are short; the pistil, on the contrary, projects considerably above the corolla. The nectar is not protected by any special arrangement of the flower itself, and is accessible even to very small insects. The stamens ripen before the pistil, and any flying insect, however small, coming from above, would assist in cross-fertilization. Creeping insects, on the contrary, which in most cases would enter from below, would rob the honey without benefiting the plant. *P. amphibium*, as its name denotes, grows sometimes in water, sometimes on land. So long, of course, however, as it grows in water, it is thoroughly protected, and the stem is smooth, while, on the other hand, those specimens which live on land throw out certain hairs which terminate in sticky glands, and thus prevent small insects from creeping up to the flowers. In this case, therefore, the plant is not sticky, except just when this condition is useful.

All these viscous plants, as far as I know, have upright or horizontal flowers. On the other hand, where the same object is effected by slippery surfaces, the flowers are often pendulous; creeping creatures being thus kept out of them, just as the pendulous nests of the weaver bird are a protection from snakes and other enemies. As instances of this kind, I may mention the common snowdrop, or the *Cyclamen*.

I have elsewhere ventured to suggest that the so-called "sleep" of flowers had reference to the habits of insects, on the ground that flowers which are fertilized by night-flying insects would derive no advantage by being open in the day; while, on the other hand, those which are fertilized by bees would gain nothing by being open at night. I confess that I suggested this with much diffidence, but it may now, I think, be regarded as well established.

Silene nutans, the Nottingham catchfly, is a very instructive species from this point of view, and indeed illustrates a number of interesting points in the relations between plants and insects. Its life history has recently been well described by Kerner. The upper part of the flowering stem is viscid, from which it has derived its local name, the Nottingham catchfly. This prevents the access of ants and other small creeping insects. Each flower lasts three days, or rather three nights. The stamens are ten in number, arranged in two sets, the one set standing in front of the sepals, the other in front of the petals. Like other night flowers, it is white, and opens towards evening, when it also becomes extremely fragrant. The first evening, towards dusk, the stamens in front of the sepals grow very rapidly for about two hours, so that they emerge from the flower; the pollen ripens, and is exposed by the bursting of the anther. So the flower remains through the night, very attractive to and much visited by moths. Towards three in the morning the scent ceases, the anthers begin to shrivel up or drop off, the filaments turn themselves outwards, so as to be out of the way, while the petals, on the contrary, begin to roll themselves up, so that by daylight they close the aperture of the flower, and present only their brownish green undersides to view, which, moreover, are thrown into numerous wrinkles. Thus, by the morning's light, the flower has all the appearance of being faded. It has no smell, and the honey is covered over by the petals. So it remains all day. Towards evening, however, everything is changed. The petals unfold themselves, by eight o'clock the flower is as fragrant as before, the second set of stamens have rapidly grown, their anthers are open, and the pollen again exposed. By morning the plant is again asleep, the anthers are shrivelled, the scent has ceased, and the petals roll up as before. The third evening again the same process, but this time it is the pistil which grows, and the long spiral stigma on the third evening takes the position which on the previous two had been occupied by the anthers, and can hardly fail to be dusted by the moths with pollen brought from another flower.

An objection to the view that the sleep of the flowers is regulated by the visits of insects, might be derived from the cases of those flowers which close early in the day, the well-known *Tragopogon pratense*, or "John Go-to-bed at Noon," for instance; still more, such species as *Lapsana communis*, or *Crepis pulchra*, which open before six and close again before ten in the morning. Bees, however, are very early risers, while ants come out much later, when the dew is off the grass; so that it might well be an advantage to a flower which was quite unprotected to open early for the bees, and close again before the ants were out, thus preserving its honey for another day.

So much for the first part of my subject. I must now pass to the second—the action of plants on insects. It would here, perhaps, be most natural to discuss the modifications which have been produced in insects by the search after honey and pollen, especially the gradual lengthening of the proboscis in butterflies, moths, and bees, to enable them to suck the honey, and the adaptation of the legs of bees to enable them to carry off the more or less dry and dusty pollen. Having, however, already treated of them elsewhere, it will be better for me to take other illustrations, and fortunately there is no lack or difficulty.

Many of the cases in which certain insects escape danger by their similarity to plants are well known; the leaf insect and the walking-stick insect are familiar and most remarkable cases.

The larvæ of insects afford, also, many interesting examples.

I will not, however, refer to isolated cases—however interesting in themselves—on the present occasion, but will take a group and see how far we can explain its various colours and markings, and what are the lessons which they teach us. For this purpose I think I cannot do better than select the larvæ of the *Sphingidæ*, which has just been the subject of a masterly monograph by Dr. Weissmann, the learned professor of Frieburg.

Let me ask you, then, to glance at the diagrams of caterpillars behind me. They are very different in colour—green, white, yellow, brown, sometimes even gaudy, varied with spots, patches, streaks, and lines. Now, are these merely casual and accidental, or have they a meaning and a purpose?

In many, perhaps in most cases, the markings serve for the purpose of concealment. When, indeed, we see caterpillars represented on a white sheet of paper, or if we put them on a plain table, and focus the eye on them, the colours and markings would seem, if possible, to render them even more conspicuous, as, for instance, in this diagram of *D. galii*; but amongst the intricate lines and varied colours of foliage and flowers, and if the insect is a little out of focus, the effect is very different.

Let us begin with the *Chærocampa elpenor*, the elephant hawk moth. The caterpillars, as represented in most entomological works, are of two varieties, most of them brown, but some green. Both have a white line on the three first segments; two remarkable eye-like spots* on the fourth and fifth, a very faint median line, and another more than four inches long. I will direct your attention specially, for the moment, to three points:—What mean the eye-spots and the faint lateral line? and why are some green and some brown, offering thus such a marked contrast to the leaves of the *Epilobium parvum*, on which they feed? Other questions will suggest themselves later, for I must now call your attention to the fact that, when they first quit the egg, and come into the world, they are quite different in appearance, being, like so many other small caterpillars, bright green, and almost exactly the colour of the leaves on which they feed. That this colour is not a necessary or direct consequence of the food, we see from the case of quadrupeds, which, as I need not say, are never green. It is, however, so obviously a protection to them, that the explanation of the green colour of small caterpillars suggests itself to everyone. After five or six days, and when they are about ¼ inch in length, they go through their first moult. In their second stage they have a white subdorsal line stretching along the body, from the horn to the head; and after a few days, but not at first, traces of the eye-spots appear on the fourth and fifth segments. There is also a second pale line running along the side. Please remark these two lines. After another five or six days, and when about ½ inch in length, our caterpillars moult again. In their third stage, the commencement of the eye-spots is more marked, while, on the contrary, the lower longitudinal line has disappeared. After another moult, the eye-spots are still more distinct, the white gradually becomes surrounded by a black line, while the centre becomes somewhat violet. The subdorsal line has almost, or entirely, disappeared, and in some specimens faint diagonal lines make their appearance. Some few assume a brownish tint, but not many. A fourth moult takes place in seven or eight days, and when the caterpillars are about an inch and a half in length. Now, the difference shows itself still more between the two varieties, some remaining green, while the majority become brown. The eye-spots are more marked and the pupil more distinct, the diagonal lines plainer, while the subdorsal line is only indicated on the first three and the eleventh segments. The last stage has been already described.

Now, the principal points to which I desire to draw your attention are (1) the green colour, (2) the longitudinal lines, (3) the diagonal lines, (4) the brown colour, and (5) the eye-spots. There are, however, some other very instructive points to which I should like to draw your attention presently, because they throw much light on this group of insects.

But to return to my five points. As regards the first—the green colour—I think I need say no more. The value to the young insect, the protection it affords, is obvious. We must all have observed how difficult it is to distinguish small green caterpillars from the leaves on which they feed. When, however, they become somewhat larger their form betrays them, and it is important that there should be certain marks to direct the eye from the outlines of the body. This is effected, and much protection given, by longitudinal lines, such as those occurring in the second stage of our larvæ. These lines, both in colour and thickness, much resemble some of the lines on leaves (especially those, for instance, of grasses), and also the streaks of shadow which occur among foliage. If, however, this is the explanation of them, then they ought to be wanting, as a general rule, in very small caterpillars, and to prevail most among those which feed on, or among grasses. Now, similar lines occur on a great number of caterpillars belonging to most different groups of butterflies and moths, as you may see by turning over the illustrations of any monograph of the lepidoptera. We have seen that they exist among the hawk moths, as for instance, in *Ch. elpenor;* they occur in many butterflies, as for instance, *Arge galathea*, which feeds on the cat's-tail grass; and among moths, as for instance, in *Pyrophila tragopoginis*, which feeds on the leaves of the "John Go-to-bed at Noon" (*Tragopogon*). Now you will find that the smallest caterpillars rarely possess these white streaks. As regards the second point also, the streaks are generally wanting in caterpillars which feed on large-leaved plants. The *Satyridæ*, on the contrary, all possess them, and all live on grass. In fact we may say, as a general rule, that these longitudinal streaks only occur on caterpillars which live on or among narrow-leaved plants. We have seen that in a later stage these lines disappear on certain segments, and are replaced by diagonal lines. In this particular species these diagonal lines are faint, but in a great many other caterpillars belonging to the most distinct families of butterflies and moths, they are conspicuous and no doubt important. Now these diagonal lines come off just at the angle of the ribs of leaves, and resemble them very much in general effect. They occur also especially in species which feed on large-leaved plants, and I believe I may say that though a great many species of caterpillars present these lines, they are rarely if ever present in species which live on grass. In this diagram are represented three of such caterpillars, one belonging to each of the three great divisions of lepidoptera, namely, that of the purple emperor (*Apetura iris*) which feeds on the oak, as representing the butterflies; that of the privet hawk-moth; and lastly, that of a moth, the Kentish glory (*Endromis versicolor*), which feed on large-leaved plants, and I believe I may say that, though very frequent, they rarely occur in species which live on grass. It might at first be objected to the view that there are many cases, as indeed in our elephant hawk-moth, in which caterpillars have both. A little consideration, however, will explain this. In small caterpillars these oblique lines would be useless, because they must have some relation, not only in colour, but in their distances apart, to the ribs of the leaves. Hence, while there are a great many species which have longitudinal lines when young, and diagonal ones when they are older and larger, there is not, I believe, a single one which begins with diagonal lines and then replaces them with longitudinal ones. You will also observe that the longitudinal lines still remain in our caterpillar on those segments which have no diagonal ones. This also often occurs, and it is striking where the lines are marked. This is also an advantage, because white lines crossing one another at such an angle have no relation to anything which occurs in plants, and would make the creature more conspicuous. It is an advantage, therefore, that when the diagonal lines are developed, the longitudinal ones should disappear. There is one other point in connection with these diagonal lines to which I must call your attention. In our species they are white, but in some cases, as for instance in the beautiful green caterpillar of the privet hawk-moth, the white streak is accompanied by a coloured one—in that case lilac. At first we might think that this would be a disadvantage, as tending to make the caterpillar more conspicuous; and in fact if we put one in full view out, for instance, on a table, the coloured lines are very striking. But we must remember that the habit of the insect is to sit on the inside of the leaf, generally near the midrib, and in the subdued light of such a situation the coloured lines beautifully simulate a line of soft shadow, such as must always accompany a strong rib, and I need not tell any artist that the shadows of yellowish green must be purplish. Moreover any one who has ever found one of

* The shaded portions, which replace the eye-spots on the other segments are an instance of the general rule that a character which appears on every two segments has a tendency to develop itself on every other segment.

these large caterpillars, will, I am sure, agree with me that it is surprising, when we consider their size and conspicuous colouring, how difficult they are to see.

The next point is the colour of the mature caterpillars. We have seen that some are green and others brown; and the green ones are obviously merely those which have retained their original colour.

Now for the brown colour. It is evident that this makes the caterpillar even more conspicuous among the green leaves than would otherwise be the case. Let us see then whether the habits of the insects will throw any light upon the riddle. What would you do if you were a big caterpillar? Why, like most other defenceless creatures, you would feed by night and lie concealed by day. So do these caterpillars. When the morning light comes they creep down the stem of the food plant, and lie concealed among the thick herbage and dry sticks and leaves near the ground, and it is obvious that under such circumstances the brown colour really becomes a protection. It might indeed be said that the caterpillars having become brown, concealed themselves on the ground; that in fact we were reversing the state of things. But this is not so, because while we may say, as a general rule, that (with some exceptions due to obvious causes) large caterpillars feed by night and lie concealed by day, it is by no means always the case that they are brown, some of them still retaining the green colour. We may then conclude that the habit of concealing themselves by day came first, and that the brown colour is a later adaptation. It is, moreover, interesting that while the caterpillars which live on plants often go down to the ground and turn brown, those which feed on large trees or plants remain on the underside of the leaves, and retain their green colour.

Thus, in *Smerinthus ocellatus,* which feeds on the willow and sallow; *S. populi,* which feeds on the poplar; and *S. tiliæ,* which frequents the lime, the caterpillars all remain green; while in the convolvulus hawk-moth, which frequents the convolvulus, *Chœrocampa nerii,* whtch feeds in this country on the periwinkle; *Ch. celeris, Ch. elpenor,* and *Ch. porcellus,* which feed on galium, most of the caterpillars turn brown.

There are, indeed, some caterpillars which are brown, and yet do not go down to the ground, as, for instance, those of *Aspilatis aspersaria,* and indeed of the *geometridæ* generally. These caterpillars, however, place themselves in peculiar attitudes, which, combined with their brown colour, make them look almost exactly like bits of stick or dead twigs.

(*To be continued.*)

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The Molecule and the Atom.*

BY PROFESSOR G. F. BARKER.

By a resolution, passed at the Detroit meeting of this Association, it was made the duty of the chairman of the Sub-section of Chemistry to prepare an address for the present occasion upon some subject of interest to the section. Before complying with this request, however, and before asking your attention to the few thoughts which I have to offer for your consideration, I desire to congratulate you upon the arrival of the one hundredth anniversary of our existence as a nation and upon the very successful celebration of this important event which is now in progress in the International Exposition at Philadelphia. While the illustrations of chemical industry there exhibited are not as extensive, for obvious reasons, as those which have been seen at previous exhibitions, yet the presence of vanillin and coniferin, of resorcin, fluorescein and eosin indicates great chemical progress even since 1873. Moreover, the excellent character and the magnificent display of pharmaceutical and industrial chemicals from our own country is a matter of pride, as foreshadowing a most brilliant future.

It has also been a matter of great satisfaction to us to receive and to welcome so many chemists of eminence from foreign countries, who came here officially either as commissioners or jurors. The names of Odling and of Lowthian Bell, of Von Wagner, Vogel and Martius, of Nordenskiold and Akerman, of Paterno, Von Baumhauer, De Wilde, Kjerulf, Kittary and Kuhlmann (fils) are well known to us in the literature of our science, and have been worthily enrolled upon the pages of the exhibition record. While it is our sincere regret that so many of them have already been called away by the pressure of home duties, we warmly welcome here to day those of them who have remained to participate in our meeting.

Another event has taken place which is of especial interest to the members of this sub-section. I allude to the formation of the American Chemical Society. The movement originated in the city of New York, and the preliminary meeting was held on the 6th of April last. At a subsequent meeting, held on the 20th, a constitution and bye-laws were adopted and a list of officers elected. The new society commences its existence under the most favourable auspices, about 200 resident and non-resident members being already enrolled upon its books. The most cordial relations exist between the society and this sub-section. To continue these relations, it might be desirable to hold the August meeting of the society jointly with that of this sub-section of the American Association.

With these preliminary remarks, I pass to the consideration of the subject which I have chosen to speak to you upon, and which I trust may prove of interest to the chemists present. I ask you to consider with me some of the ideas which exist to day in science concerning the molecule and the atom, especially as they appear when viewed from the chemical standpoint. Said Professor Cannizzaro, in his Faraday lecture:* "I do not hesitate to assert that the theory of atoms and molecules ought to play in the teaching of chemistry, a part analogous to that of the theory of vibrations in the teaching of optics." Clearness of conception, on our part, being essential to clearness of statement before those whom we instruct, an attempt to state this theory of atoms and molecules cannot fail to be of service in so far as it is successful.

The best evidence for the existence of matter is its necessity. Hence, eminent authority defines it as "that which is essential to the existence of the known forms of energy, without which, therefore, there could be no transformations of energy."† The divisibility of matter is at once a metaphysical and a physical question. It is obvious everywhere that masses of every form of matter known—saving, perhaps the light ether—are capable of division with more or less readiness. But is there any limit to this division other than the imperfection of the means employed? Here physics and metaphysics are at variance, and the former boldly avers that there is a limit. A fragment of salt, for example, sustains subdivision only to a certain extent. Divide it but once again, and the salt as such disappears, and in its place we have the two new substances, sodium and chlorine. This limiting particle is called a molecule. It is the smallest particle of any substance which can exhibit the chemical properties of that substance. The aggregation of molecules constitutes a mass; hence the molecule is the physical unit—the ultimate particle or centre of the physical forces.

What now in the light of modern physics is the

molecule? What is its size and weight? And is it at rest or in motion? The relative size of material molecules has long been known, and forms the starting-point of chemical investigation. The law of Avogadro, enunciated by him in 1811,* but more recently placed by Boltzmann on a surer foundation,† asserts that in equal volumes of all gases there is the same number of molecules. The proof of this law is found jointly in that of Boyle, published in 1662,‡ and in that of Charles, published a short time after.§ The former of these laws states that the volume of any gas is inversely as the pressure to which it is subjected; and the latter that the co-efficient of dilatation by heat is nearly the same in all permanent gases. Since all gases are alike in these respects, they must be alike in their molecular constitution, upon which the phenomena depend. But if it be true that equal volumes of all gases contain the same number of molecules, it is also true, as a necessary deduction, that all gaseous molecules must be of the same size. The relative size of molecules is therefore determined.

The determination of the absolute size of a molecule, even approximately, would have been but a few years ago an entirely hopeless task. But now the problem has been attacked and solved, and numbers are given for the sizes of molecules which agree excellently well even when deduced from widely different data. The best results of this sort which have been obtained are those of Thomson and Maxwell.|| To comprehend their reasoning it is necessary to premise the heterogeneity of matter. "A body is called homogeneous," say Thomson and Tait,¶ "when any two equal, similar parts of it, with corresponding lines parallel and turned towards the same parts, are undistinguishable from one another by any difference in quality." But if we apply this definition to matter, without any limitation as to the size of the parts, there is no reason to believe that any form of matter known to us is homogeneous. More than thirty years ago Cauchy showed, from a mathematical investigation of dispersion, "that in palpably homogeneous bodies, such as a glass of water, contiguous portions are not similar when their dimensions are moderately small fractions of a wave length of light."** This result, it is evident, is the same with that obtained above, when by continual sub-division of a mass the molecule was reached as a final particle. The heterogeneity of matter then, in this sense, lies in the fact that it is made up of molecules separated by intervening spaces—a structure without which dispersion is impossible. Now, by the discovery of Cauchy just given, inasmuch as we know the length of a wave of light, we may, by assuming the small fraction spoken of, arrive at an approximation to the size of a molecule. Taking the wave length at 1-2000 of a millimeter, and assuming that the distance from the centre of one molecule to the centre of the next cannot be less than 1-10,000 part of this value,†† we have one-twenty-millionth of a millimeter as the diameter of the molecule; *i.e.*, the measure of the coarse-grainedness of matter.

A second method of determining the approximate size of material molecules is one which we owe to Sir William Thomson.‡‡ It is founded on the important fact—asserted by Volta, but denied until put beyond dispute by Thomson—that when a zinc and a copper plate are placed in contact, either directly or by means of a connecting wire, the zinc is positively and the copper negatively electrified. Since, therefore, the two bodies attract each other, it is clearly possible, by measuring the attraction, to calculate the amount of work which would be done by their coming together. A plate of zinc and a plate of copper one centimeter square in metallic connection separated by one-hundred-thousandth of a centimeter attract each other with a force of two grams. The work done in bringing these plates into this position is two-hundred-thousandths of a centimeter-gram. The work done by electric attraction in forming a pile of fifty thousand such plates would be two centimeter-grams. But this work by the law of Joule is equivalent to an amount of heat sufficient to heat the mass 1-16,120 of a degree. If, however, the space between the plates be reduced to a hundred-millionth of a centimeter, the heat generated would raise the mass by 62°; and if to a four-hundred-millionth, by 99 times the amount required to warm it 1° C. Now, as this is a far greater amount than that actually produced by their chemical union, the inference is a fair one that we have exceeded the limit of the heterogeneity in these metals. Hence the coarse-grainedness of this matter, and hence the molecular magnitude does not probably fall below one thirty-millionth of a millimeter.

A third calculation of the size of molecules is founded on data obtained from the soap-bubble film, and is also due to Thomson.* The force with which such a film contracts—shown commonly by using the stream of air issuing from the stem of a pipe on the bowl of which is such a bubble, to blow out the flame of a candle—is a measure of the work done in stretching it in units of force per unit of breadth. In the case of pure water, this contractile force is about sixteen milligrams weight per millimeter of breadth. Hence, the work done in stretching it, measured in millimeter-milligrams, is sixteen times the increase of area in square millimeters, provided only that the contractile force is not reduced by this diminution in thickness of the film. To prevent the fall of temperature which would necessarily accompany the drawing out of this film, it has been demonstrated that about half as much more energy in the form of heat must be supplied to it. Hence, for every square millimeter added to the area of a film of water whose temperature remains constant, its total energy is increased by twenty-four milligram-millimeters. A film one millimeter thick requires, to extend its area ten thousand and one fold, an expenditure of work for each square millimeter of the original film—or each milligram of its mass—of 240,000 millimeter-milligrams. Its thickness would thus be reduced to a ten-thousandth of a millimeter, and the temperature of the whole would be raised by the heat equivalent of this work by only half a degree Centigrade. But experiment proves that there is no diminution of the contractile force with this thinness of film, and hence that the number of molecules in its thickness is considerable. If, however, we extend the film yet more, so that its thickness is reduced to a twenty-millionth of a millimeter, the work expended in doing this is two thousand times greater, and its heat equivalent would be 1130 times that required to raise its temperature by 1° C. Now, since far less work than this would be sufficient in the form of heat to destroy the liquid as such (and of course its contractile force), and convert it into vapour, it is clear that the contractile force of a water-film diminishes greatly before it attains a thickness of one twenty-millionth of a millimeter. As such a diminution is inconceivable so long as there are several molecules in the thickness of the film, it follows that there are not several molecules in the twenty-millionth of a millimeter.

Parliamentary and Law Proceedings.

CHARGE OF MANSLAUGHTER AGAINST A CHEMIST'S ASSISTANT.

At the Glamorganshire Assizes, on Friday, the 23rd inst., before Mr. Justice Mellor, George Whitfield Williams, chemist's assistant, Grangetown, Cardiff, on bail, was charged with causing the death of Archibald Wm. Hy. Hayward, at Cardiff, on the 6th November, by the administration of a dangerous drug. Mr. H. Allen prosecuted; Mr. Bowen Rowlands defended

Mr. E. Hayward stated that the child whose death prisoner was alleged to have caused suffered from fits about three weeks after its birth, and he consulted Dr. Edgar Jones as to its health. Dr. Jones recommended the child being sent to the Infirmary, and for some time it was treated as an out-patient. When the child was about two months old, witness went to Mr. Yorath's shop, where the prisoner was assistant, in order to get some syrup of rhubarb with a little laudanum in it for the child, as it was then suffering from scab on the head, and he had previously been accustomed to use medicine of a similar description for his children when they were suffering from that disorder. The prisoner said he had no syrup of rubarb, but he could put a little laudanum into some syrup of poppies, and give him that. He asked witness whether that would do. Witness said, "I do not know." Then the prisoner said that all the syrups were much about the same thing, and gave him a pennyworth of syrup of poppies with a few drops of laudanum in it. He labelled the bottle "Syrup of Poppies.—Poison," with a printed dose upon it. He told witness that the dose would be half a teaspoonful. On leaving the shop prisoner said, "Be careful; I think you had better not give the child half-a-teaspoonful, as I have given you nearly ten drops of laudanum." Nothing further was said in the shop, and when witness reached home his wife administered a dose of the medicine to the child, giving it barely half a teaspoonful. The medicine was given to the child in his presence, and he repeated to her the caution he had received from the prisoner. The medicine was given to the child for some time, and witness went to Mr Yorath's several times for a similar quantity of the syrup, always taking the same bottle (his own) to be filled. Finding the child became no better, during subsequent visits to Mr. Yorath's witness told the prisoner that the chemist from whom he had had the medicine before used gradually to increase the laudanum in it, and asked him whether he could increase it in the same manner. Accordingly the prisoner gave him an increase of laudanum in the syrup, gradually increasing the quantity of laudanum up to 20 drops. The child received the medicine for about five months—up to the date of its death in November, in fact. It gradually wasted away. In cross examination witness said that Dr. Jones had told his wife that in his opinion the child was not likely to live. That was about two weeks after its birth. The doctors at the Infirmary said the same thing. Another of his children living had, he had been informed, got at the bottle, and taken some of the syrup the deceased child was taking. At the coroner's inquiry into the circumstances of the death of the child, both witness and his wife were charged with manslaughter.

Mrs. Hayward, wife of the last witness, said that she took the child to Mr. Yorath's shop on several occasions, and the prisoner told her to administer half a teaspoonful as the dose of the poppy syrup, and he said once or twice that as he had began to give the stuff she would have to continue it. Once it began to scream in the shop a good deal, and the prisoner noticing it was very thin and delicate, said he thought it must be in a decline. In cross-examination witness said that the other child who took the medicine drank nearly half the syrup, and its eyes become dull, and it went pale afterwards. She took it down to the chemist's, and he told her to keep it awake, and it would be all right.

Dr. D. E. Jones spoke to being called in to attend the child when it was three weeks old, and subsequently. It was a delicate infant, and he recommended its being taken to the Infirmary. After its death he saw the child, and the result of a *post-mortem* examination was the conclusion that the cause of death was suspicious. He did not find sufficient disease to account for death. The child was very much emaciated, and the lungs and brain were congested. From the appearance of the body, he thought the child had been poisoned by opium. Opium poisoning was very difficult to trace in *post-mortem* examination, and he should not like to swear positively to the results of his examination in such a case.

Without proceeding further, the Judge directed the jury to find a verdict of not guilty. The case was only one of suspicion, and they could only act in such a case as this when the cause of death was assigned with certainty. Accordingly the prisoner was discharged.—*South Wales Daily News.*

POISONOUS CONFECTIONERY.

At the Manchester Police Court last week two confectioners were summoned under the provisions of the Sale of Food and Drugs Act for selling confectionery stained with a substance injurious to health. The purchase of the sweets having been proved,

Mr. Estcourt, the city analyst, said he had found them to contain in one case one fifth of a grain and in the other two-fifths of a grain per ounce of chromate of lead, which was a poison, and would produce the bright yellow colour on the sweets. Witness produced a sample of confectionery coloured yellow and red with vegetable matters, which he said were quite innocuous. The chromate of lead was undoubtedly injurious to health, even in small quantities.

Dr. Legh, medical officer of health for the city, said that the injurious effects of taking the chromate would be cumulative, and might probably end in partial paralysis. The result of a large dose would be that of an irritant poison, vomiting, etc.

Mr. Smith, who appeared for one defendant, admitted the sale, and pleaded that the defendant was unaware of the injurious nature of the chromate of lead, which was commonly used in the trade, and was known by the name of "chrome." Since the proceedings were taken, he had discontinued its use, and was using the vegetable matters.

Mr. Headlam said it was the duty of everybody who used colouring matter to put into food to ascertain very carefully what it consisted of, for everybody knew that a large proportion of colouring substances were poison. As this was the first case under the Act that had come before him, he inflicted the lowest penalty, *i.e.*, £5 and costs in each case.

Review.

MANUAL OF CINCHONA CULTIVATION IN INDIA. By Dr. G. KING, M.B., F.L.S. Office of the Superintendent of Government Printing, Madras.

The author, who is well known as the superintendent of the Royal Botanical Gardens at Calcutta and of cinchona cultivation in Bengal, has presented in the work before us a most interesting and complete history of the cinchona cultivation in India from the commencement of the enterprise until the year 1876. It is divided into seven chapters, in which are traced successively the collection of seeds and plants in South America; their introduction, after numerous failures, into India; the difficulties met with in course of cultivation; the results of chemical and physiological experiments upon the cinchona trees; the different modes of collecting and harvesting the bark;

and the methods of extracting the alkaloid adopted in different localities.

One third of the work is occupied by appendices which present in a tabular form the stock of trees in the Nilghiri and Sikkim plantations; the expenditure and revenue; the prices realized at sales of cinchona bark in London; the quantities of alkaloids supplied to the Indian Government from 1867 to 1873, with the cost of the same, reports upon the action of the mixed alkaloid supplied by the Sikkim quinologist, and meteorological observations made at the several Government plantations.

The style throughout is remarkably clear and concise, and the large amount of information contained in this manual is so well arranged that not only are the author's views readily understood, but one feels after its perusal that the whole subject has been treated in a most masterly manner. The plan which has been adopted of placing a marginal note against each paragraph, renders it exceedingly easy to refer to any point of a particular interest.

The first two chapters, although very necessary to the completeness of the history, are to a certain extent introductory.

The third chapter commences with the cultivation of the cinchona plant in India, Ceylon and British Burmah, and it is here that the reader will look more particularly for details concerning the district which has been more especially under the notice of Dr. King.

In this chapter the author points out that *C. officinalis* and *C. Pitayensis* do not thrive at Sikkim, while *C. Calisaya* promises to do well, and *C. succirubra* flourishes wonderfully, and can be cultivated to any extent that is desirable. By reference to the appendix it will be seen that *C. micrantha* and *C. officinalis* have ceased to be planted, while the worthless *C. Pahudiana* has not been planted since 1866. A new seedling form containing much quinine has, however, received much attention, and in April, 1875, there were 21,000 plants of it under cultivation. Fortunately this valuable species grows well in Sikkim and at a higher level than the *Calisaya*.

A tolerably good idea of the value of the Sikkim plantations may be formed by comparing the statement in the third chapter with the appendix E, in which the area under cultivation at Sikkim is given as 1939·442 acres. Of this amount about three quarters is devoted to red bark, while of the remainder 219 acres contain pale bark, 164 *C. Calisaya*, 31 *C. micrantha*, 4 *C. Pahudiana* and 7 the new variety of *Calisaya* above alluded to.

At the Nilghiri plantations there is shown to be a much less proportion of red bark, nearly one-half of the whole area being planted with pale bark and its more valuable varieties, the remainder being chiefly *C. succirubra*, with a comparatively small proportion of *C. micrantha* and *C. Pitayensis*.

The tendency of the reports, so far as they have gone, appears to show that red bark is by far the hardiest and most easy to cultivate, succeeding in most places where it has been planted, while pale bark flourishes best in the Nilghiris and Ceylon, *C. Calisaya* at Sikkim, and *C. Pitayensis* at the Nilghiris only.

From the fourth chapter, we learn that the careful observations which have been made have added largely to our knowledge of the best method of cultivating the different kinds of cinchona, and that these plants each require a particular method of treatment.

The author expresses his opinion that the fungoid diseases to which the cinchona plants are occasionally subject are by no means likely to prove so serious as at first anticipated by Mr. McIvor, and that they are chiefly due to insufficient drainage of the soil. Full particulars as to the various methods of propagation and the species to which each one is best adapted, as well as of all the details necessary to successful cultivation, will be found in this chapter.

The next chapter, relating to the chemistry of the bark crop, summarizes the results obtained by chemical examination and by the commissions appointed to report upon the relative medical value of the different alkaloids. One point here is especially worthy the notice of experimental chemists. Mr. Broughton's experiments are shown to have led to the conclusion that amorphous quinine is the alkaloid first formed, and that as the bark becomes older, this alkaloid is replaced partly by crystallizable quinine, and partly by cinchonidine. Other points affording valuable hints to the cultivator are that the amount of alkaloids in the bark is increased by deprivation of light; that a high temperature favours the production of cinchonidine, but diminishes that of quinine; that red bark yields its maximum proportion of alkaloids in its ninth year, and that the most vigorous and rapidly growing trees yield the richest bark. The age at which pale bark yields the maximum amount of quinine does not appear to have been ascertained.

In the sixth chapter the processes of mossing, coppicing and uprooting the tree are severally described and commented on. Dr. King does not fully concur with Mr. McIvor as to the value of the mossing process, and however successful it may be at the Nilghiris it had failed entirely at Sikkim from a most unexpected cause. In every tree mossed at Sikkim the renewing bark has been regularly eaten by ants! It is singular that this does not appear to have been the case with those trees which were barked but not mossed. The author seems of opinion that the best plan of procedure is to plant thickly and to cut in alternate rows at four years old and uproot the other rows at eight or nine years old, when the trees would begin to deteriorate.

By this means he considers that the expense of clearing would be avoided and that, including the root bark, the yield would be as good if not better than by any other process yet devised.

The last chapter gives a detailed account of the process employed by Mr. Broughton, at the Nilghiris, in making his "amorphous quinine," but since his product cost more than commercial quinine, and the factory has been closed, it seems almost unnecessary to have entered so fully into its details.

The process introduced by Mr. C. H. Wood, at Sikkim, is one which appears to incur much less expense than that used by Mr. Broughton, and is extremely simple. It consists in exhausting the bark by four macerations with water acidulated with hydrochloric acid, precipitating with caustic soda, redissolving the crude precipitate in dilute sulphuric acid, adding a solution of sulphur in caustic soda to decolorize the liquor, and precipitating the filtered solution by caustic soda. The result is the Cinchona febrifuge.

In order to insure as much uniformity as possible, one kind of bark (red) only is employed, and the root, stem and branch bark are mixed together, in as nearly as possible the proportions in which they are yielded in the plantations. Dried bark is used, and thus the process can be carried on throughout the year. It is found that dried bark yields a much better product than green bark, and quite as large a quantity.

The macerations being made by rotation in sets of three casks, the solutions are obtained in as concentrated a state as possible. The factory consists of wooden sheds and the apparatus of beer barrels, thoroughly cleansed and with the heads removed, and an iron vessel for the soda solution; and Coolie labour is used. The hydrochloric acid is obtained in Calcutta at a cost of 3½ annas per pound, and the caustic soda from England at the rate of £15 to £20 per ton. The febrifuge is to be sold at a rupee an ounce, and the quantity which it is estimated can be turned out, viz., 4800 pounds, will, it is considered, pay the whole cost of the plantations and manufacture for one year. The quinologist intimates that if the product prove of value as a remedial agent, the process could be considerably modified to produce greater economy, although that would involve the use of permanent buildings and machinery.

The full details of the process we have sketched are appended in the form of a fly leaf to Dr. King's manual.

The average composition, in 100 parts, of alkaloid from Sikkim red bark appears to be: crystalline quinine, 15½; amorphous quinine, 17; cinchonine, 33½; cinchonidine, 29; colouring matter, 5; and it is considered that it will be produced at a cost of less than one rupee (two shillings) per ounce. If this be the case and the reports upon its utility continue to be favourable, the object of the Government plantations will to a certain extent have been a success at Sikkim.

By reference to appendix B, however, it will be observed that in 1875, the amount of quinine and other alkaloids purchased by Government had not materially decreased, and that larger quantities had been supplied to Bengal than to any other presidency.

In conclusion, it must be admitted that Dr. King has provided a manual which, for usefulness, conciseness, clearness and scientific value may safely be said to be without an equal in the subject of which it treats. The only drawback is that it is not easy to obtain a copy, only a limited number having been printed.

Phosphorized Cod-Liver Oil.

Sir,—In the *Pharmaceutical Journal* of the 10th inst., Mr. Martindale mentions the difficulty of preparing Phosphorized Cod-Liver Oil by dissolving the phosphorus in the cod-liver oil direct, instead of in almond oil, owing to the liability to oxidation of the phosphorus, and the formation of pellicles on the surface of the oil and subsequent dark brown deposit on the sides and bottom of the bottle.

During the last twelve months I have prepared a fair quantity of phosphorized cod-liver oil by dissolving the phosphorus in a small quantity of cod-liver oil, and immediately the phosphorus is taken-up by the oil throwing it into the bulk of cold cod-liver oil. I have noticed that if the concentrated oil is allowed to cool for even twenty or thirty seconds, the dark resinous pellicle begins to form, and very quickly increases, but by mixing it quickly with the bulk, I never see a trace of solid matter. I bottle it off for retail, and have always found it remain perfectly bright, forming no deposit whatever, but some that I had from my wholesale druggist deposited in about a month. I placed two ounces of my oil in a six ounce bottle about last September, and now although the oil is not sweet, it is perfectly bright, and the bottle free from deposit.

Respecting the phosphorized cod-liver oil being more palatable than an equivalent dose of phosphorus administered in other forms, on account of the deposit detracting from its strength, I may mention a circumstance that occurred a month or two ago. A customer of mine, who has had plain cod-liver oil from me regularly, came in one evening, and seeing that I was busy with several customers, he took up a bottle of oil, placed it in his pocket, and paid me, for he would not allow me to wrap it up. At the time, I forgot that I had placed some bottles of phosphorized oil near the plain oil, and I afterwards found that he had taken one of them. He called in a few days after, and said he found his mistake when he got home, but thought he would like to try the phosphorized oil, and after taking it each morning, he said he had the taste of lucifer matches in his mouth the remainder of the day. My business does not allow me the time to go deeply into the subject as Mr. Martindale and some other gentlemen have, and there may be some objections to the process I have adopted, which I have not perceived, and if so, I hope some gentleman will kindly point it out.

W. B. Baynham.

6, Rye Lane, Peckham, S.E.

Glycerinum Tragacanthæ.

Sir,—On opening the Journal last week, I was pleased to see the name of J. C. Thresh in conjunction with "the Excelsior pill excipient," Glycerinum Tragacanthæ. I lost no time in digesting the whole thoroughly and now must ask you to give me an opportunity of expressing an opinion. I will set aside Mr. Thresh's valuable experiments, and judge the letter as a condemnation of glycerine and tragacanth as an excipient, for such the last paragraph of letter suggests.

After five years' experience (dispensing alone) with glycerine and tragacanth, I am fully prepared to support those gentlemen who have taken the trouble to commend this preparation to pharmacists and to strongly deprecate the assertions of Mr. Thresh in his last paragraph.

True that Mr. Thresh had a variety of masses made with this excipient and that he found they did not turn out as he had anticipated, this does not prove the worthlessness of the excipient. For my part this would be the last excipient I should think of using for masses I intended to keep as masses; it would suggest itself that a gummy material like tragacanth with moisture would on keeping become very hard and friable. I should say glycerine alone would be far better. Again, Mr. Thresh condemns it on account of it not making the pills of the Pharmacopœia. From my experience, and I do not think it to be so very different from other assistants', where a dispenser sends out one Pharmacopœia pill he sends out a dozen of private formulæ and under those circumstances shall Mr. Thresh say that he (the dispenser) can always find a more suitable excipient? I say most decidedly—No! I admit that the judgment of the dispenser must always be brought to bear in the choice of excipients, but I assert that out of a dozen prescriptions, ten may be judiciously made with Glycerinum Tragacanthæ.

With regard to the dissolving of the pills in warm water, I admit that made with Glycerinum Tragacanthæ, and kept for a considerable time, they do not dissolve so readily as if made with treacle or syrup, but I am not arguing for the use of this preparation in place of the excipients of the Pharmacopœia, but to support what has been said in favour of it in dispensing. When a patient brings a prescription for ½ or 1 doz. pills it is not his intention to keep them locked up for six months or so, but, as the label invariably directs, to take one every or every other night. Under these circumstances let the mass be made as hard as you can,—it will dissolve in hot water.

When I think of the hundreds of masses of valerianate of zinc, oxide of zinc, carbonate of soda and reduced iron, etc., I have made with this excipient, I feel sorry to see the subject handled so roughly and apprentice-like.

I hope Mr. Thresh will forgive my speaking so strongly remembering it was he who first made the assertions.

I would recommend to all pharmacists to rub a little pulv. tragac. with glycerine to form a paste, place it in a pot and in the course of the day it will become a jelly. I am sorry I cannot give a formula, having always made it by rule of thumb; a little practice will suffice. Pills made with this are easily worked up and rolled and in ten to thirty minutes become quite hard.

Suum Cuique.

Union Street, Bristol.

W. S. Rogers.—The regulations could probably be obtained by application at Apothecaries' Hall.

F. C. S.—The summing up of Mr. Baron Bramwell is printed in the *Pharmaceutical Journal* for February 5, 1876, p. 639.

W. Atkinson.—The decision lies with the Inland Revenue authorities; we cannot say whether they would sanction the practice, either by a grocer or a chemist and druggist.

"*Chemicus.*"—There are Schools of Pharmacy in Paris, Lyons, Nancy, Montpellier, and other French cities.

M.—We think the subject is hardly suited for discussion in a pharmaceutical journal.

"*Statim.*"—Probably they could be bleached by treating them with a weak solution of sulphurous acid or chloride of lime.

Communications, Letters, etc., have been received from Professor Dymock, Mr. Fairlie, Mr. John, Mr. Atkinson, Professor Dragendorff, Mr. Tichborne, Mr. Hooper, T. A. H., Chemicus, Negator.

Erratum.—In the Answers to Correspondents on p. 788, col. i., line 2 from bottom, for "℥ij Pulv. Acaciæ," read "ʒij Pulv. Acaciæ."

MEDICINE MEASURES.*

BY B. S. PROCTOR.

Early in last year I drew attention, in the correspondence columns of the *Pharmaceutical Journal*, to the errors resulting from the use of spoons as measures for doses of medicine, with the view of eliciting such expressions of opinion as would enable some practical suggestion to be selected for general adoption. I now return to the subject, having given it deliberate thought and having come to a definite conclusion upon the mode which appears to me to be most desirable and most practicable for getting rid of the difficulty.

I feel no hesitation in saying that the subject is one of grave importance and one which must sooner or later press for a radical change,—the sooner in consequence of the growing disposition to order medicines of virulent character in concentrated form.

So much has been said by others as well as by myself about the discrepancy in the sizes of spoonfuls, that there will be little difficulty in agreeing to the general statement that it is desirable to abandon the use of "spoonfuls" altogether, though it must be admitted that such a change cannot be accomplished all at once.

Any attempt to modify the quantity to be understood by the word "tablespoonful" would only increase the confusion; and to use the term "tablespoonful" to signify a quantity which only half fills a customary tablespoon is no less inconsistent than it is unsafe. It is highly desirable, therefore, to take any step which will promote the adoption of expressions which are free from ambiguity and the use of measures which closely approach to exactness. The different sized spoonfuls should cease to be used *even as the names of quantities*, and the terms half-ounce, quarter-ounce and drachm, should take their place. As it is, we have the tablespoon graduation on the glass measures indicating a quantity which does not fill a tablespoon—the glasses are divided as they should be, into ounces and drachms, but they are marked as they should not be, by tablespoons and teaspoons.

When medicine is ordered by tablespoonfuls, I would write directions in tablespoonfuls, but with the reputed equivalent in ounces written in parenthesis, and I would give a simple cheap measure with the medicine, of such capacity as to hold one dose, and labelled "this measure holds one dose of the medicine," or words to that effect. When this precaution is taken it appears to me that mistake or inaccuracy is almost impossible.

If the prescription directs "℥ss ter die," the label is written "Half an ounce thrice a day," and the half ounce measure is supplied with the medicine and labelled as above. When two or more mixtures are ordered at once with different doses, I would supply a separate measure for each, and mark upon the label of each measure the name of the mixture for which it is to be used; thus one measure may be marked "cough mixture" and another "tonic." Or the measures may bear a number corresponding with the registration number of the mixture.

A correspondent in a recent number of the *Pharmaceutical Journal* prefers to use the term "accurate tablespoonful" rather than half ounce, and thinks that more full directions should be branded upon the measures. Personally I do not feel satisfied with the expression "accurate spoonful," or "measured spoonful" as was suggested by a former correspondent, or with any other words implying that a spoon may be used for measuring. I am quite prepared to find a great diversity in the opinions of pharmacists as to the best mode of expressing what is desirable either on the measure or on the bottle of medicine, and this very circumstance would deter me from advising makers to adopt any full particulars on a burnt-in label.

I anticipate that each pharmacist will prefer to print labels according to his own ideas, and if in course of time physic makers and physic takers should come to a common understanding, a generally approved label burnt into the earthenware will no doubt be the result.

Last April I suggested that the Council of the Pharmaceutical Society should give consideration to this subject, and that it would be desirable to have from them an expression of disapproval of the use of the term spoonful as a measure for medicine, but that when such terms are used by medical men the pharmacist should interpret the tablespoonful to mean half an ounce, the dessertspoonful two drachms, and the teaspoonful one drachm, unless some other interpretation was clearly indicated, and that they should express disapproval of the use of the term "spoonful" on a label as the interpretation of the ounce or drachm mark when such are used by the prescriber. But in the absence of any action on the part of the Council, I now simply make known for the edification of my brethren what course I have concluded to pursue failing any instructions spoken with authority upon these points.

[*The discussion on this paper is printed at p.* 820].

ELIXIR OF MONOBROMATED CAMPHOR.

BY J. MUNDAY.

As monobromated camphor is a chemical which is likely to become a favourite remedy, especially if it could be given in a liquid form, I have made other experiments since my last note, which was inserted in the Journal of the 3rd of March.

I find that glycerine has not sufficient sweetening properties in itself to overcome the nauseous taste, I now therefore introduce the following formula, which is more agreeable and seems to answer well.

Monobromated Camphor.	℈i
Sp. Cinnamon (1 in 50)	ʒxv
Red Elixir (U. S.)*	ʒxx
Syrup q. s. to make ℥iv.	

Mix the sp. cinnamon, red elixir, and syrup together, and add the monobromated camphor, and dissolve in a flask in a water-bath, taking care to use no more heat than is absolutely necessary, or else the monobromated camphor will recrystallize.

The product contains two grains in each half-ounce, and I think will be found a convenient form for administering this drug where it is preferred in a liquid form.

I also give the formula for a compound elixir of

* See *Pharm. Journ.* [3], vol. iv., p. 682.

the above, which is being prescribed a good deal by the profession here, under the name of

Elixir Camph. Monobrom. Co.

Croton Chloral	gr. iij
Tr. Gelsem. Semper.	♏x
Monobromated Camphor	gr. ij
Sp. Cinnam. (1 in 50)	ʒis
Red Elixir	ʒiss
Syrup ad	℥es

Dissolve the croton chloral in the sp. cinnamon, mix with the red elixir, gelsemium and syrup, and dissolve the monobromated camphor as directed for the simple elixir.

14, *Rue de la Paix, Paris.*

COD FISHING IN NORWAY.

When the old year in England has but a few hours to live, when days are short and dark, and when we take refuge from the outer cold before cheerful fires in holly-decorated rooms—at that time very different scenes are presented in many homes in Norway. There all is vigorous activity. Men are anxiously examining and repairing fishing nets; children are disentangling and stretching fishing lines; women, more active than either, are mending leather clothes, washing woollen shirts, making large rye loaves, rolling out flat flakes of oatmeal bread as thin as wafers, watching the contents of hot ovens, and, as it were simultaneously, packing up quantities of butter, cheese, and dried meats. All this because in a few days the father and breadwinner of the family is about to depart on his annual venture as a fisherman to the Lofoten Islands. By the middle of January all is ready. The weather is then day by day carefully watched until, on the very first favourable opportunity, implements, clothes and provisions are hurried on board the fishing boat, the crew take a hasty farewell of their families, and sail away to dare stormy seas and hostile coasts.

Lofoten is the name of a group of islands extending in a south-westerly direction from 68° 36′ to 67° 25′. The channel that lies between these islands and the Norway coast is called the Westfjord; it has a wide open mouth towards the ocean in the south west, narrowing upwards in the opposite direction towards the north east. The permanent population of these islands is about 25,000 souls. With the exception of a few small farms in the larger islands, only three industries are followed by the inhabitants, fish catching, fish dealing, and lodging letting; these they pursue with equal ardour. In every bay that is at all protected from the violence of Atlantic storms, the native fishermen and fish merchants have built large numbers of huts. These huts, constructed of rough boards and covered with turf, consist generally of two rooms, arranged to hold from six to twelve persons, that is, one or two crews. Round the walls of the living-room is fixed a settle or wooden bench, known as the board-bed, while in the other are stored nets, ropes, lines, clothes, provisions, and empty barrels for roe or oil. As these huts are occupied by a large number of persons, out of all proportion to their size, who moreover habitually hang up their wet and dirty clothes to dry, the air within is naturally extremely bad. But the fishermen care little for this, being well content with a hard bed and a sound roof, knowing well that less fortunate companions outside are passing the night on deep snow, with no other covering than a sail or an inverted boat. Well might these hardy mariners say in the words of the Pilgrim Fathers, "It is not with us as with men whom small things can discourage." Early in the morning all are astir. Before going out to fish every man partakes of hot coffee for breakfast, prepared by one of the boys. Dinner later in the day consists of dried meats with bread or potatoes, and supper of hot fresh fish or boiled fish liver with bread.

The boats engaged in fishing with nets are from 36 to 40 feet long, 9 to 10 feet wide, with a depth of not more than 3 feet. They are provided with only a single mast, about 24 feet high, carrying one large square sail. But each boat has as well ten or twelve oars, by means of which her sturdy crew can propel her against an adverse wind. For fishing with lines, smaller and less costly boats are used.

The crew, usually consisting of five men and a boy, in the first place elect one of their number to be captain. No general of an army is more strictly obeyed than is the captain of a fishing boat, for his men well know that their success, property and often their lives, depend on prompt obedience to his orders. For these reasons in selecting a captain, experience, energy, knowledge of the channels, and coolness in danger, are alone taken into account. Age has no influence, except that no fisherman above the age of fifty is taken as captain, for he is by that time supposed to have lost something of his strength and courage. Still less does property blind the judgment, for it frequently happens that the servant is made captain while the master, who has aided the choice, has to row or work the sail. The selection once made the captain becomes a real chief, not only over the boat at sea, but on shore over all purchases and all sales as well as before the public authorities. No sooner is a fisherman elected to be captain than his gait becomes prouder, his dress smarter and his language more polished than before, conscious that he is raised above the common crowd. Notwithstanding his dignity, the position of captain is only one of honour, and he has no greater share in the produce of the catch than any other of the crew.

In the month of December the first shoals of cod (*Gadus Morrhua*) usually begin to appear on the western banks of the islands, arriving from the open sea. These are soon followed by great masses of fish. But as these western outside shores are shallow, the ports few, and the whole coast exposed to the frequent fury of the North Sea, not more than from six to eight hundred boats venture on the hazards of this early fishery, and their take seldom exceeds five or six millions of fish.

In the mean time the inhabitants on the inner or eastern side, protected from northerly winds, and favoured with many bays of refuge, examine their shores day by day with baited hooks, to discover if the precursors of the dense shoals of cod have yet appeared in the Westfjord, and great is the public exultation when the joyful news of their arrival is announced. This important event takes place generally in the latter end of December, but not before the middle of January do the fish arrive in great masses.

On their approach, the shoals usually choose for their entrance the openings between the islands

Moskö and Röst, or between Röst and Vœrö, all situated at the south-west extremity of this group of islands. No sooner have they entered the West-fjord, than they distribute themselves in prodigious numbers in order to select suitable places for spawning. As the area is great and the fish capricious in their choice, it is not possible for the keenest captain to foresee where the densest masses of cod will accumulate. Generally they make for the eastern and more protected shores of the islands, and for the upper end of the Fjord, but in some seasons they have been known to remain on the outside western coasts altogether.

Although the fish arrive so early in the year, spawning does not actually take place till March, and not then till late in the month. It occurs not at the bottom of the sea, as is popularly supposed, but in the middle of the water, which is made turbid by the clouds of roe and milt. At this particular time the fish are very restless and go easily into the nets.

Codfish are taken by the Lofoten fishermen by three methods:—1, with hand lines; 2, with set lines; and 3, with nets.

Hand lines, requiring small capital and producing small results, are only employed by the poorest fishermen. These are satisfied with 50 fish to each man per day, although occasionally they will capture double that number. They bait with herrings, salt or fresh, and when these are all gone, with the roe of the fish they have caught. Sometimes when the shoals of cod are very thick and dense, the men adopt another method, also with a single line but requiring no bait. Providing themselves with a long cord armed with a large and sharp hook at its extremity, they sink it into the swarming masses below, having first attached to it a couple of feet above the hook, small fishes of tin for the purpose of attracting the cod by their glitter. The fishermen then jerk the hook sharply upwards, occasionally securing a curious fish though cruelly wounding many others that are not taken.

Set line fishing requires larger apparatus: a boat, a crew, and from 500 to 3000 hooks baited at once. The hooks are attached to fine snoods of hemp or cotton, which in their turn are suspended on long lines; each boat puts out at least twenty-four of these lines, every line carrying more than a hundred hooks. Set line fishing usually begins in the afternoon, but in any case only at the time and in the place prescribed by the officers appointed at each station for the purpose. The baited hooks are generally suspended near the bottom, but if there is reason to believe that the fish have risen, as they sometimes will, the lines are shortened and the bait raised to the required height by means of glass floats. They are then left all night. On the following morning the lines are taken in and the crews are well content with an average take of 50 to 60 fish daily on each set of 120 hooks.

Net fishing requires larger capital, and is only followed by the more wealthy fishermen, who provide both nets and lines to be used according to circumstances. When the fish are fat, and especially during spawning season, they will hardly take any notice of the bait; then is the time the nets are used. Every boat carries at least 60 nets of from 10 to 20 fathoms deep. These nets are suspended in the water from floats of wood, cork, or glass. Hollow glass floats are preferred and are almost exclusively used at Lofoten, a most useful application of that water-resisting material, invented by Mr. Christopher Faye, of Bergen. Sixteen to twenty nets bound together in one length are set out in the afternoon, and, weather permitting, are taken up the following morning. A catch of from 500 to 600 cod is considered satisfactory; but if this number is largely exceeded, part are left in the nets till the afternoon, because the boats could not safely carry so heavy a freight together with the crew and wet nets.

The total take of cod by these various methods has ranged during the last few years from fifteen to twenty-five millions of fish per annum.

The cod being thus caught, the first thing the fishermen do after coming on shore is to have their dinner. That concluded, they proceed to clean and prepare their catch.

The livers reserved for the preparation of medicinal oil are all very carefully examined, and those that are poor, have sustained injury, or have portions of gall adhering are removed. The selected are then thoroughly washed and afterwards dried. The fishermen, many of whom make the oil themselves or sell to larger makers, put these prepared livers immediately into open barrels where the oil slowly exudes, and rising to the top is removed with large spoons. It is then when quite cold filtered three or four times through filtering paper and the preparation is complete. Nothing more remains but to pour it into tin cans or oak barrels, and it is ready for market. This oil is described as of a straw yellow, has nearly no smell nor taste, and is known as "natural medicinal oil."

In the mean time other fishermen having carefully sorted, washed, and dried their livers, place them in a pot of tinned sheet iron. This tinned pot is then put into a larger iron pot half full of water, which on becoming heated causes the livers immediately to begin to give out their oil. Other makers introduce steam from a boiler between the two pots, and others let the steam act directly on the livers. The first yield by these methods of regulated heat is also removed by spoons, filtered when cold, and reserved for medicinal use, under the names of "steam-boiled medicinal" and "ordinary bright." The after yield is used in medicine, though somewhat redder: it is called "bright brown."

Finally, those portions of liver that will not dissolve by themselves or by a mild heat, are roughly boiled down to yield dark brown or tanners' oil, the black residue being used with other fish refuse for manure.

As for the fish itself, when the liver and the roe have been carefully removed, the backbone dissected out, and the entrails and head thrown into a waste heap, it is cut open down to the tail, whereby it becomes quite flat, and in that state is either packed away between layers of salt, or is hung up to dry in the cold open air till it becomes as hard as wood, to be henceforth known as—stockfish.

The cod liver oil prepared at Lofoten finds its way in the first stage of its travels to Bergen, where it begins to arrive in May. Here live the merchants who have advanced money, implements and provisions to many of the fishermen early in the season, and who now take a lively interest in the pecuniary results. Many of the fishermen require no advance, and these sell their produce to the highest bidder. The care taken at Lofoten in preparing the medicinal oil is by no means extended to the dark brown or tanners' oil. This is made all along the coast indiscriminately from the livers of cod, coal-fish, ling, tusk, halibut, haddock, skate, and even of the shark. But before exportation every barrel is examined by an official expert at Bergen, who with an iron instrument makes a mark close to the bung indicating the quality.

Early in April the fish begin to leave the Westfjord, and soon after retire towards the open sea in such multitudes that by the end of the month both fish and fishermen have departed; the fishers' huts, so lately swarming with life, are silent and empty, and the Lofoten Islands are left to their permanent inhabitants for the remainder of the year.

Five years ago the number of men engaged in these fisheries exceeded 27,000, owning more than 4000 vessels. In contrasting this amount of labour with its results—fifteen to twenty-five millions of cod fish—it should be remembered that the tempestuous weather usually prevailing in these northern latitudes during the winter months often prevents the fishermen going to sea for weeks together, and that a season that has permitted fishing on an average of two days a week may be considered a favourable one.

Although the cod fisheries of Lofoten are the largest and the most renowned, Norway has many others of great value along her far-stretching seaboard. Opposite the Throndhjem Fjord, and from that to Cape Stat, there are three or four miles from the shore several very rich fishing banks, where cod collect in enormous shoals to spawn, observing the same periods as the Westfjord fish. Again, opposite the Varanger Fjord, from the 59th to the 62nd parallel of latitude, are many good cod banks. From Aalesund now annually go forth daring crews with decked vessels, who fish in the deep sea at a distance of ten or twelve miles from the shore. Their lines are set on a bank at a depth below the surface of from 150 to 200 fathoms, that is to say, from four to six times the height of the London Monument. Exceeding these in importance is a relatively new fishery in the far north in Finmark, which now promises to rival even that of Lofoten itself in its yield. In the latter part of February the appearance of millions of sea-gulls fluttering along the surface of the ocean, with the spouting and blowing of numerous whales in it, announce to the scanty population of Finmark and Cape North, that great shoals of capelin (*Mallotus villosus, Osmerus arcticus*) are approaching the shore. Following these, it is well known, will also be millions of cod fish pursuing their favourite food. So valuable has this fishery become that many of the men after finishing the Lofoten season, now flock to Finmark, and have lately succeeded in taking an after catch of from twelve to fifteen millions of fish. In this enterprise they are favoured by the later migration of the northern shoals, which always continue on those shores till the end of May, and in the Varanger Fjord until June. But in Finmark the harbours are bad and the weather more violent and destructive than in Lofoten; were it not for this the take would be much larger than it is, as the shoals of fish in Finmark appear to rival those of Lofoten in magnitude.

Thus the Norwegian fisheries produce in great abundance not only an invaluable remedy for one of the most fatal maladies that afflicts humanity, but they supply many tons of wholesome and cheap food to the less affluent populations of the whole of Europe. These industries result in a hardly earned income to these hardy Northmen of not less than £2,500,000 per annum, a magnificent sum for a country possessing a population of barely two millions of souls.

The facts in the preceding paper have been gathered by Mr. Robert Howden from an official report, by Mr. Hermann Baars, of Bergen, written originally in the German language, to illustrate the Norwegian Industries at the Vienna Exhibition, in 1873. Subsequently this report was translated into English by Mr. Alfred Sharpe, of Christiania, for the purpose of explaining the same industries at the Philadelphia Exhibition last year. Mr. Baars is a gentleman of intelligence and high culture. He is in no way connected with either pharmacy or commerce, so that his object has been not to inform pharmacists, or any other class, so much as to make a general report on the National Industries of his country. From this work the above particulars have been gleaned; if on the one hand we may regret the absence of some technical details on the other we are largely indebted to him for much new and exact information that is now, through his intelligent industry, submitted to the English reader.

DISTINCTIVE TESTS FOR CARBOLIC AND SALICYLIC ACIDS.*

According to Almén the delicate reaction of ferric chloride with salicylic acid may also be used to distinguish carbolic from salicylic acid in very dilute solutions. Both acids give a violet colour with the iron salt, but, while the utmost limit of perceptibility of the tint in the case of carbolic acid is one in 3000, the colour produced by salicylic acid remains intense in dilutions of one in 100,000, and is still discernible even in solutions containing only one in 1,000,000. The most sensitive test for both acids is said, by Almén, to be the well-known Millon's reagent, prepared by dissolving mercury in ordinary fuming nitric acid and diluting with two volumes of water. The less acid the reagent is, the more delicate a test it is for both salicylic and carbolic acids. Five or ten drops of Millon's reagent are added to about twenty c.c. of a solution of these acids, and the mixture is heated to boiling, which causes the precipitation of a yellow basic salt of mercury. To the boiling hot liquid as much nitric acid is added as is required to redissolve the precipitate. In presence of either acid, the solution assumes an intensely red colour, which increases in depth by standing. The limit of perceptibility of this reaction is one in 2,000,000 for carbolic acid, and but little less for salicylic. In dilutions of one in 400,000, the colour appears instantaneously, in higher dilutions only after the lapse of ten to fifteen minutes. The best method to detect the presence of carbolic in salicylic acid or in salicylates is probably the well known reaction with ammonia and sodium hypochlorite, consisting in the production of an intensely blue colour, which turns red on addition of an acid, and is restored by alkalies. Free chlorine and the presence of free acids interfere with the reaction, especially in warm solution; hence an excess of sodium hypochlorite, especially in very dilute solutions, must be avoided, and a sufficient quantity of ammonia must be added to maintain an alkaline reaction. Solutions of phenol, containing one in 5000, give the reaction at once; dilute solutions, containing one in 30,000, after about fifteen minutes; and even still more dilute solutions, up to one in 50,000, after twenty-four hours. Solution of salicylic acid, even concentrated (one in 1000), does not give this reaction, which enables us therefore to detect the presence of phenol in salicylic acid.

MANUFACTURE OF ARTIFICIAL BUTTER.*

BY HENRY A. MOTT.

The first matter to be attended to when a good product is to be manufactured is cleanliness. I start off with this most important point, to which the strictest attention must be paid.

Washing Process.—The fat, on arriving at the factory, is first weighed, and then thrown piece by piece into large tanks containing tepid water, care being taken to place all pieces covered with blood in a separate tank to be washed. The fat in the tanks should now be covered entirely with tepid water, and left at rest for about one hour, when the tepid water should be removed and the fat thoroughly washed with cold water, then covered with fresh cold water, and allowed to rest for one hour longer; the water is then again removed, and the fat thoroughly washed, for the last time, with fresh cold water, when it is ready for the next operation.

The *Disintegrating Process* consists in disintegrating the fat by passing it through a "meat hasher." To do this, the fat in the tank is removed by means of a wooden car to the side of the hasher, where it is cut with a knife into pieces about five or six inches square. Piece by piece it is introduced into the hasher, which, by means of the revolving knives within, cuts the fat very fine and forces it through a fine sieve at the opposite end, and finally out of the machine and into a tub. Care must be taken not to introduce the fat into the hasher too rapidly, as the sieve or knife is apt to snap, for it requires considerable power for the disintegration, which is, of course, accomplished by steam power.

Melting Process.—The fat, now in a disintegrated state, is removed to the melting tank, care being taken not to introduce into the tank any of the water which is forced out of the fat during the disintegrating process. The fat is then heated by means of the water surrounding the tank, until the temperature reaches 116° F., when the steam which heats the water is turned off. The water surrounding the tank being much warmer than the molten fat, increases the temperature of the fat to about 122° to 124° F., when the fat completely melts. During the whole operation, from the time the steam is turned on until the melted fat is allowed to rest, the fat must be continually stirred, so that an even temperature may be maintained. The adipose membrane of the fat, called "scrap," separates and settles to the bottom, on leaving the melted fat at rest, and a clear yellow oil floats on top, covered by a film of white emulsion of oil with the water contained in the fat.

When the scrap has completely settled, the thin layer of emulsion is skimmed off, and the clean yellow oil is drawn and received in wooden cars, which, when filled to within one inch of the top, are removed to some place, to allow the oil to granulate. Care must be taken in drawing off the last portion of the oil not to allow any of the scrap to mix again with it. It is better to receive the last portion of the oil and scrap in a small galvanized iron can, and allow it to cool by itself, and when cool to melt it over again by placing the can in one of the washtubs and surrounding it with water heated to about 125° F., and thus separate from the scrap all the oil that is possible.

It sometimes occurs that the scrap refuses to settle, and rises to the surface, forming a layer on top of the clear oil. If such be the case, the melted fat and scrap must be stirred up together for at least ten or fifteen minutes, and then allowed to settle by standing, which it will generally do. If it does not, then it should be again stirred and allowed to stand; and if another failure follows, a quart or two of salt must be thrown on the scrap and the mixture stirred, when the scrap will soon settle to the bottom after standing.

An acid solution of the active principle of the stomach of a calf was used for some time, as proposed by Mége, in the melting process. It was thought to coagulate the "scrap" and cause it to settle more rapidly. Experiments have shown it to be unnecessary, however. The melting process, when conducted with success, occupies about two or three hours. The oil in the cars will require at least twelve or twenty-four hours or more to granulate, and the temperature of the room should be about 70° F. This is a very important operation, and must not be hurried, otherwise the stearin in the fat will not have time to crystallize.

Press Process.—The car containing the solidified oil from the melting process (which for convenience hereafter I will call refined fat) is removed to the press room, which room is kept at a temperature between 85° F. and 90° F.

The refined fat must not be so solid that it cannot be worked with the fingers with ease; if it is, it must be left in the press room until it softens. When in the right condition, it is packed in cloths, set in moulds to form packages about 4 in. wide, 8 in. long, and 1½ in. thick. These packages are then placed on galvanized iron plates in the press, at equal distances apart. The plates are piled one above the other until the press is entirely filled, when the packages are subjected to a slight pressure, which must be increased very gradually, and only after the oil pressed out begins to flow very slowly. The oil is received in a tin vessel, which, when filled, is replaced by another. The pressing is continued until no more oil can be obtained at the temperature of the room. The pressure is then removed and the plates unpacked, when cakes of pure white stearin are obtained, having the dimensions of about 8 in. × 5 in. × ½ in. The stearine, after the removal of the cloths, is ready for sale. The cloths are put into one of the tanks containing hot water, until all the oil and stearin are melted off, when they are washed in another tank, and then hung up to dry. The oil and stearin in the first tank are solidified by means of cold water, collected and sold as soap grease.

The oil obtained from the press is removed to some cool place, until it assumes a temperature of about 70° F., when it is ready for the next operation.

The oil now at the proper temperature (70° F.) is removed to the churning room. One hundred pounds of oil are introduced into the churn at a time, with from fifteen to twenty pounds of sour milk. About 3 or 2½ ounces of solution of annatto, to which has been added from ½ to ¾ of an ounce of bicarbonate of soda, may now be added, and the whole agitated for about ten or fifteen minutes, until milk, colouring matter, and oil are thoroughly mixed together, when the whole mixture is withdrawn from the churn, through a hole at one end, and allowed to fall into a tub containing pounded ice. As the oil flows on the ice, it must be kept in constant motion until the tub is filled with solidified oil, when another tub is put in its place. The graining is by this simple process completely prevented. The solidified oil, which has a slight orange* colour, is left about two or three hours in contact with the ice in the tub, when it is dumped on an inclined table, where it is crumbled up so that the ice may melt and leave the solidified oil, which is then crumbled up fine by hand, and about thirty pounds of it at a time are introduced into a churn, with about twenty to twenty-five pounds of churned sour milk, and the whole agitated for about fifteen minutes, when the solidified oil takes up a certain percentage of the milk, as also the flavour and odour (which were by the ice washed out from the first churning), and pure butter is produced. This is now removed from the churn to the working table, where, after standing and draining for a time, it is salted, to the extent of three-quarters to one ounce of salt to the pound of butter.

After proper working and standing for a sufficient length of time, it is packed into firkins, and is ready for sale. The butter thus produced contains nothing foreign

* Abstracted from a paper in the *American Chemist* for December, 1876.

* The colour is made purposely a slight orange colour, so that in the last churning process just sufficient colour is destroyed to leave the product with the proper colour.

to the very best of butter, and this has been the object to which I have devoted so much attention. When prepared as above, it has always found a ready sale in the market, as its keeping qualities are far superior to butter made by churning milk or cream. The percentage of butyrine, caprine, caproine, etc., it contains is very small (being derived from the milk in the last churning process), not sufficient to make the butter become rancid when decomposed, but quite sufficient to give to the butter the so-much prized flavour and odour.

I sent a sample of butter, made by the above process, to the Hon. X. A. Willard, the President of the New York State Dairymen's Association, who is considered one of the highest authorities in this country on everything connected with dairy products. He says, in a letter to me on the subject: "The sample of butter sent is far superior to any I have seen, in flavour and texture. I have shown it to a number of experts in butter, and they were greatly surprised at its flavour. If you could produce a more waxy texture in the article, it would puzzle *some* to distinguish it from genuine butter." This from a man of acknowledged ability is sufficient to endorse all that I have said with respect to the product. With respect to the waxy texture—this property the artificial product acquires on standing a short time.

Composition of Artificial Butter.—I have subjected a number of samples of artificial butter to analysis, and find:—

Analysis of Artificial Butter.

Constituents.	Good Sample.	Good Sample.	Sample not so good.
Water	12·13	11·88	19·68
Butter—solids . . .	87·87	88·12	80·32
	100·00	100·00	100·00
Fats . . (Olein, Palmitin, Stearin, Butyrin, etc.)	82·41	81·64	75·39
Casein	·63	·86	·91
Salt	4·83	5·62	4·02
Colouring matter . . .	Trace.	Trace.	Trace.
	87·87	88·12	80·32

I find an analysis of artificial butter by Dr. Brown, which I compare in the following table with an average of my first two analyses given above, as also with an analysis of butter made from cream.

Butter Analyses.

Constituents.	Artificial Butter. By Dr. Brown. I.	Artificial Butter. Average of two analyses. By Mott. II.	Butter made from cream. By Mott. III.	Same as III. Calculated to 5·225 per cent. of salt.
Water	11·25	12·005	12·29	11·827
Butter—solids . .	88·75	87·995	87·71	88·173
	100·00	100·000	100·00	100·000
Fats (Olein, Palmitin, Stearin, Butyrin, etc.)	87·15	82·025	86·01	82·765
Casein	·57	·745	·19	·183
Salt	1·03	5·225	1·51	5·225
Colouring matter .	Trace.	Trace.	...	...
	88·75	87·995	87·71	88·173

It will be seen, by comparing the first three analyses in the above table, that the difference in the percentage of fat in my analyses and either of the others is owing to a greater percentage of salt (this is easily seen by comparing No. III. with the last analysis), which element may be reduced or augmented in the manufacture to suit the taste and requirements. The amount of casein is also a trifle higher in the artificial than in the natural product, but not greater than the average amount usually present.

I have carefully calculated the proportion of the different fats with respect to their melting point.*

Analyses of the Fats of Butter.

(*Partly calculated*).

Constituents.	Fats from Natural Butter.	Fats from Artificial Butter.
Palmitin ($C_{51}H_{98}O_6$) . .	20·33	22·32
Stearin ($C_{57}H_{110}O_6$) . .	42·77	46·94
Olein ($C_{57}H_{104}O_6$) . . .	27·71	30·42
Butyrin ($C_{15}H_{26}O_6$), Caproin ($C_{21}H_{38}O_6$), Caprin ($C_{33}H_{62}O_6$), Caprylin ($C_{27}H_{50}O_6$) . .	9·19†	·32
	100·00	100·00

By comparing the constituents of these two analyses, it will at once be seen that the difference in the per cent. of the different constituents arises from the very small amount of butyrine, etc., in the artificial product, and it is for this reason that the artificial butter keeps so much better than natural butter. There is sufficient of the butyrin in the butter to give it the odour, flavour, and taste of butter, but not sufficient, when decomposed into butyric acid, to render the product rancid.

I have calculated the amount of the individual constituents in the fat in my analysis of natural butter and my average analysis of artificial butter, and substituted the same, with the following results:—

Complete Analysis of Butter.

(*Partly calculated*).

Constituents.	Natural Butter.	Artificial Butter (when properly made).
Water	11·827	12·005
Butter—solids	88·173	87·995
	100·000	100·000
Palmitin ($C_{51}H_{98}O_6$) . .	16·826	18·307
Stearin ($C_{57}H_{110}O_6$) . .	35·399	38·502
Olein ($C_{57}H_{104}O_6$) . . .	22·934	24·954
Butyrin ($C_{15}H_{26}O_6$), Caproin ($C_{21}H_{38}O_6$), Caprin ($C_{33}H_{62}O_6$), Caprylin ($C_{27}H_{50}O_6$) . .	7·606	·262
Casein	·183	·745
Sodic Chloride (Salt) . .	5·225	5·225
Colouring matter . . .	...	Trace.
	88·173	87·995

* The specific heats were not considered.

† The butyric acid was ascertained by analysis, which is approximately correct. All volatile fats stated are calculated as butyrin. Heintz has found besides the above fats butin and myristin.

The Pharmaceutical Journal.

SATURDAY, APRIL 7, 1877.

Communications for the Editorial department of this Journal, books for review, etc., should be addressed to the EDITOR, 17, *Bloomsbury Square.*

Instructions from Members and Associates respecting the transmission of the Journal should be sent to MR. ELIAS BREMRIDGE, *Secretary*, 17, *Bloomsbury Square, W.C.*

Advertisements, and payments for Copies of the Journal, MESSRS. CHURCHILL, *New Burlington Street, London, W. Envelopes indorsed "Pharm. Journ."*

MILK OF SULPHUR PROSECUTIONS.

As predicted by some of our correspondents, the lawyers have made short work of the milk of sulphur question. The decision of the magistrates who convicted Mr. MARSHALL at Runcorn, last December, of selling as milk of sulphur "a drug that was not of the nature, substance and quality of the article demanded," being appealed against, the case was heard on Tuesday last at the Knutsford Quarter Sessions by a very full bench of magistrates, including Lord DE TABLEY, Sir GILBERT GREENALL, M.P., Hon. W. EGERTON, M.P., and Sir RICHARD BROOKE, with Mr. HORATIO LLOYD, barrister, as Chairman. The sessions commenced on Monday, and this being an adjourned appeal case stood first on the list, but there were rumours afloat that the prosecutors were not eager for the fight. When the case was called on there was nobody present to open the proceedings. The inspector was there and the analyst was there, but there was no one to represent the Runcorn magistrates from whose conviction the appeal took place. On being questioned by the Chairman, the inspector and the analyst declined to take any responsibility beyond that which attached in the one case to the collection of the sample and in the other to the analysis and certificate which represented the composition of the sample. The counsel, Mr. CLEMENT HIGGINS (instructed by Mr. GLAISYER, LL.B., on behalf of the Chemists and Druggists' Trade Association), who appeared for the appellant, stated that his client was there with a large number of scientific and other witnesses, who had been brought there at considerable expense, and as several other cases similar to this were standing over to be decided in accordance with the decision in this which was intended to be a typical case, he was anxious not to allow the previous decision to be reversed merely in default of the plaintiffs appearing, but to have the evidence given and judgment recorded on the merits of the case. It was therefore arranged that the case should stand over until the next day, Tuesday, when Mr. MARSHALL appeared as counsel for the plaintiffs.

In addition to the evidence previously given at Runcorn, several fresh witnesses were provided on this occasion by the appellant, who was prepared to show in the most conclusive manner that milk of sulphur containing sulphate of lime is a recognized and officially authorized medicine which the public have for centuries been accustomed to use, that in numerous cases this medicine is not only found to be more easy of administration, but medicinally more efficacious than any of the other preparations of sulphur, and that it has therefore been and still is a favourite remedy which the public and some members of the medical profession require and ought to be supplied with. Members of the drug trade, both wholesale and retail, were called to prove what they understood by the term "milk of sulphur," and what the public expected to receive and were alone satisfied to be supplied with when they asked for milk of sulphur. Evidence of long established custom in these respects among some of the leading London houses with aristocratic connections, as well as among those who principally supply the poor, was adduced or ready for production. In addition to this, evidence was given by Mr. PEMBERTON, of Birmingham, to the effect that medical men, in the treatment of diseases, especially of the rectum, for which sulphur is used, find that milk of sulphur containing sulphate of lime has a specific and beneficial effect which precipitated sulphur does not produce, that the latter by its action on the coats of the intestine often causes irritative diarrhœa, while the former, being modified in its action by the mild aperient properties of the sulphate of lime, relaxes without irritating or purging.

When the evidence had arrived at this point, the Bench adjourned for their luncheon, before proceeding with the examination of Professor REDWOOD, Messrs. SIEBOLD and WOOLLEY of Manchester, Mr. JOSEPH INCE, and other witnesses who were present, and when they returned the chairman said they had availed themselves of the opportunity afforded by their absence from the court for conferring together with reference to the bearing of the evidence already given, and they thought that although the absence of the term milk of sulphur from the Pharmacopœia might be considered to justify the county analyst in the course he had adopted, yet the Bench could not for one moment doubt, after the evidence of Mr. PEMBERTON and others, that in the trade and in the medical profession there were two distinct substances known as *lac sulphuris* and *sulphur præcipitatum*, and that they were supplied to the trade and the public by those names as two distinct things. They therefore thought the case had not been made out, and that the appellant had not committed an offence within the Act. The conviction would therefore be quashed. The appellant's counsel applied for costs, and the chairman said the Bench had considered that point, but as they could not blame the analyst they thought the decision ought not to carry costs.

We feel assured that this decision, emanating from so distinguished a bench of county magistrates will be received as a satisfactory settlement of the question with reference to which so many discordant opinions have been expressed. The public may now continue to take themselves or to give to their children the milk of sulphur they have been used to and prefer, while druggists may satisfy the requirement of their customers in this respect without the fear of a prosecution or the charge of dealing in an adulterated article.

We trust that in future it will be the uniform practice of druggists to act in accordance with the judicial decision thus given, and to recognize *lac sulphuris* and *sulphur præcipitatum* as two distinct substances.

THE ANNUAL MEETING OF THE CHEMICAL SOCIETY.

In another column we print the official report of the anniversary meeting of the Chemical Society, and in a bracketed paragraph we have added Mr. Kingzett's remarks more *in extenso*. It will be seen from reading this report, that there exists a considerable amount of dissatisfaction among a large body of the Fellows regarding the government of the Society, and we believe that we have not yet heard the last of it.

The Society now numbers 919 Fellows, and it is complained in the report that the increase in the number of Fellows during the past year has fallen off compared with a few previous years; the Council therefore regards the state of the Society's income with considerable apprehension! It might be thought that with the manufactories existing in England for the production of science teachers, there could scarcely exist a lack of applications for election into the Chemical Society; unfortunately, however, the President stated that the fact of a man calling himself a science teacher is sufficient, generally speaking, to cause his rejection. However this may be, outside the Society itself the act of characterizing the blackballing as unjust and indiscriminate will be regarded as unconstitutional. The President said he took the responsibility of this statement upon himself; but he did not lay before the meeting the grounds upon which he made it. We quite agree with Professors Williamson and Odling that any interference with the exercise of balloting by the Fellows is unwise and injudicious, for if a Fellow is of opinion that any candidate does not merit election, he has an undoubted right to vote against him; if in fact the Fellows are not to use the ballot box for the purposes it is intended to serve, why have it at all? It cannot be denied that there are some in the Society who ought not to have been elected, and it would appear that the Council has recognized this fact, since it has proposed alterations in the form of recommendation for election, and the wording of the obligation.

We fail to see on what grounds the Society can expect or hope to increase its numbers *ad infinitum*; but this is certain, that the number of applications for elections is greater than ever, which shows that recent purifying influences originating within have been appreciated outside the Society itself.

As regards the Research Fund of the Society, which now amounts to more than £3000, we understand it is intended to sink this capital and to use merely the interest for the encouragement of research. Now, although some of this money which has been given to the Society takes the form of shares or stocks that cannot be realized under the imposed conditions, yet we feel strongly that it would be wise to spend, where possible, the capital itself, for otherwise the money grants will be so small that they will scarcely assist workers in the prosecution of research; moreover we think that the sooner money is wisely distributed, the sooner will it be replaced.

As regards the complaints made by certain gentlemen about the treatment of papers by the Committee of Publication, there appears to be good cause. Papers that are not to be published as they stand ought not to be read as such, that is to say, the control or censorship to be exercised, should be exercised before the reading of the paper. To modify an author's statements after a paper had been read, and to request him to adopt conclusions which do not follow from experimental premises, is not only inappropriate, but, moreover, exceedingly unjust and pernicious. The Fellows of the Society complain that they do not well understand the authority by which the Committee of Publication exists, nor how it seeks to attain its objects.

Those who complain are active working Fellows of the Society, and have, we are convinced, its interests at heart, and they desire to be well governed, but at the same time governed wisely and fairly, and the sooner such a state of things be realized the better for the future welfare of the Chemical Society.

THE BENEVOLENT FUND.

The interest excited by the desire to make the Benevolent Fund Dinner to be held next month a success, has produced a very liberal offer from a member of the trade, which we should be glad to see utilized. A letter that has been received by the Secretary was read at the Council Meeting last Wednesday, containing an offer to give £100 to the Benevolent Fund if forty-nine other persons would volunteer before the 15th of May to give a similar sum; or £50, with ninety-nine other donors. It is also conditional that the donations shall not be given in the names of firms, nor larger sums than those specified given in one person's name.

EARLIER CLOSING.

We take the earliest opportunity of stating that it is intended to hold on Wednesday week, the 18th inst., at 8 p.m., in the Lecture Theatre, 17, Bloomsbury Square, which has been lent for the occasion, a meeting of the Chemists and Druggists of London, for the purpose of discussing what steps can be taken to further reduce the number of hours during which their shops are kept open. At present we are not informed as to who is to preside, or the exact order of business to be followed, but we hope that the gentlemen who have taken the initiative will receive a hearty and general support manifested by a crowded meeting.

Transactions of the Pharmaceutical Society.

MEETING OF THE COUNCIL.

Wednesday, April 4, 1877.

MR. JOHN WILLIAMS, PRESIDENT.

MR. WILLIAM DAWSON SAVAGE, VICE-PRESIDENT.

Present—Messrs. Atherton, Atkins, Betty, Bottle, Cracknell, Frazer, Greenish, Hampson, Hanbury, Hills, Owen, Robbins, Sandford, Schacht, Shaw, and Stacey.

The minutes of the previous meeting were read and confirmed.

NOMINATIONS FOR COUNCIL AND AUDITORS.

The Secretary reported that there had been *thirty-five* nominations to fill the fourteen vacant seats on the Council, and the following *twenty-three* nominees had signified their willingness to accept office if elected:—

Atherton, John Henry, Long Row, Nottingham.
Baildon, Henry C., 73, Princes Street, Edinburgh.
Betty, Samuel Chapman, 6, Park St., Camden Town, N.W.
Bottle, Alexander, 37, Townwall Street, Dover.
Brown, William Scott, 113, Market Street, Manchester.
Bulgin, William, 22, New Road, Gravesend.
Churchill, Walter John, 46, New Street, Birmingham.
Cracknell, Charles, 217, Edgware Road, W.
Cubley, George Arthur, 4, High Street, Sheffield.
Deane, James, 17, Pavement, Clapham Common, S.W.
Gostling, Thomas Preston, Diss.
Greenish, Thomas, 20, New Street, Dorset Square, N.W.
Guyer, James Brett, 11, Strand, Torquay.
Hampson, Robert, 205, St. John Street Road, E.C.
Hanbury, Cornelius, Plough Court, Lombard St., E.C.
Richardson, John Geo. Fredk., Friar Lane, Leicester.
Rimmington, Felix Marsh, 9, Bridge Street, Bradford.
Robbins, John, 372, Oxford Street, W.
Shaw, John, 24, Great George Place, Liverpool.
Stacey, Samuel Lloyd, 300, High Holborn, W.C.
Vizer, Edwin Bennett, Church Rd., Cliftonville, Brighton.
Williams, John, 16, Cross Street, Hatton Garden, E.C.
Wills, Geo. Sampson Valentine, 62, Lambeth Road, S.E.

The following *twelve* nominees declined to accept office, if elected:—

Andrews, Frederick, 23, Leinster Terrace, Hyde Park, W.
Barclay, Thomas, 252, Moseley Road, Birmingham.
Bell, Charles Bains, 6, Spring Bank, Hull.
Carteighe, Michael, 172, New Bond Street, W.
Davenport, Horace, 33, Great Russell Street, W.C.
Earle, Francis, 22, Market Place, Hull.
Frazer, Daniel, 113, Buchanan Street, Glasgow.
Hills, Walter, 338, Oxford Street, W.
Morson, Thomas, 124, Southampton Row, W.C.
Postans, Arthur William, 35, Baker Street, W.
Reynolds, Richard, 13, Briggate, Leeds.
Squire, Peter Wyatt, 277, Oxford Street, W.

The Secretary also reported that the following five members had been nominated for election as auditors and had declared their willingness to accept office if elected:—

Andrews, Frederick, 23, Leinster Terrace, Hyde Park, W.
Barron, Frederick, 2, Bush Lane, Cannon Street, E.C.
Hodgkinson, William, 127, Aldersgate Street, E.C.
Horner, Edward, 20, Bucklersbury, E.C.
Squire, William, 5, Coleman Street, E.C.

The PRESIDENT said he could not but express the regret which he felt sure was shared by the whole of the members of the Council, at the determination of Mr. Frazer not to allow his name to be submitted to the Society for re-election. Mr. Frazer would carry with him the sympathies of all his colleagues and he hoped that at some future time he would see his way to return to the Council.

Mr. FRAZER briefly replied, explaining that domestic reasons made it impossible for him at present to remain a member of the Council.

ELECTIONS.

MEMBERS.

Pharmaceutical Chemists.

Haydon, William Frederic......Birmingham.
Littlewood, John Oscroft ......Sutton-in-Ashfield.
Smith, George ....Monkwearmouth.
Turner, William Spencer.. ......Hingham.

ASSOCIATES IN BUSINESS.

The following, having passed their respective examinations, being in business on their own account, and having tendered the subscription for the current year, were elected "Associates in Business" of the Society:—

Minor.

Barry, Frederic ....Shaftesbury.
Billinge, Mark ....Hyde.
Cattell, Thomas Bellamy.........Birmingham.
Dampney, Richard Shephard ...London.
Day, John......................... ...Dewsbury.
Embley, John ....Brierfield.
Forth, William Pilcher ....South Norwood.
Hoyles, George.....................Hull.
Knight, George James......... ..London.
Nicholson, Walter Joseph ......Birmingham.
Pell, John ....Woolston, near Southampton.
Sargent, John Charles...........Sevenoaks.

Modified.

Harding, Samuel Jervis ....Audlem.
Robertson, John ....Edinburgh.
Scaife, Samuel ....Manchester.
Shemmonds, John ....Bournemouth.

ASSOCIATES.

The following, having passed the Minor examination, and tendered their subscription for the current year, were elected "Associates" of the Society:—

Barron, William ....Leamington.
Cullingford, Louis James.........Bletchingley.
McKnight, John ....Dalston.
Taylor, Charles Edward ....Lancaster.

APPRENTICES OR STUDENTS.

The following, having passed the Preliminary examination, and tendered their subscriptions for the current year were elected "Apprentices or Students" of the Society:—

Bristed, John ....Margate.
Cowie, John ....Glasgow.
Crompton, Wm. Wolstenholme..Bury.
Cuthbert, Sidney Agar............Bedford.
Ellis, John William......... .....Abergele.
Ellis, Richard ....Knaresborough.
Field, George W....................Cambridge.
Foot, Ernest George...............Plymouth.
Hancock, Edwin ....London.
Lowe, Sam Peter .. ..Sheffield.
Sims, George Samuel ....Derby.
Stephens, Stephen ....Llandilo.
Thomas, Frederick William ...Dowlais.
Wright, George......................Sheffield.

REPORTS OF COMMITTEES.

FINANCE.

The report of this Committee was received and adopted and several accounts ordered to be paid.

The Auditors' report was also presented.

Mr. SCHACHT suggested that in future the salary of the Librarian, or at any rate a portion of it should appear under the head of "Library," so that the cost of that branch of the Society's operations should be more clearly seen.

Mr BOTTLE also suggested that the items of expenditure on the North British Branch should be given more in detail.

The Auditors' report was received and adopted.

BENEVOLENT FUND.

The report of this Committee included a recommendation of the following grants:—

£10 to the widow of a registered chemist and druggist, aged 67. Applicant's late husband had received two grants of £15 and £10 respectively.

£10 to the widow of a registered chemist and druggist, whose case had been previously considered and deferred for further inquiries.

£15 to the widow of a registered chemist and druggist, whose husband had been in business for thirty-four years.

The report and recommendations were received and adopted, after a long discussion had taken place as to the propriety of removing from the list of annuitants the name of one of the recipients who had been guilty of misconduct. It was ultimately decided not to proceed to such an extreme measure at present.

LIBRARY, MUSEUM, AND LABORATORY.

This report included that of the Librarian, showing the average attendance in the Library, during the previous month, to have been, in the day, 22; evening, 13. Circulation of books, in town, 151; country, to twenty-four places, 42.

The following books were recommended for purchase:—

Brunton's 'Tables of Materia Medica;' Burbidge's 'Cultivated Plants;' Vogl's 'Falschen Chinarinden.'

Mr. Sainsbury had presented two copies of a book just published by him, 'Human Interests, Reflections, etc.'

The Curator reported the attendance in the Museum to have been on the average, day, 18; evening, 8. Also, that the Hanbury Herbarium had been used for reference, and that the Indian Drug Collection had been dried and placed in the museum.

Professor Attfield had reported 73 entries in the laboratory since the commencement of the session; 43 students being now at work.

Professor Redwood had reported the number of students in his class to be the same as last month. Also that the electric light apparatus was nearly ready, and that he intended shortly to give a lecture illustrated by it.

Professor Bentley had reported that the number attending his class was 38.

The report of the Committee was received and adopted.

The SECRETARY read a letter from Professor Redwood, stating that the addition of the electric light would enable him to make use of much of the valuable apparatus belonging to the Society, which had hitherto been of little use. It was decided to request Professor Redwood to give his first lecture to the Society, aided by the apparatus, on Wednesday evening, May 2nd.

HOUSE.

This Committee had held a meeting. A second ventilating shaft had been placed in the library, and was found to work effectively. Sundry recommendations which referred to the better ventilation of various parts of the premises were made, and an estimate for the same, amounting to £13 10*s*., was presented.

The report was received and adopted.

The PRESIDENT reported that the work in the octagon aboratory was nearly finished.

Mr. BETTY asked for an account to be presented at the next meeting of the total sums expended on education and educational arrangements during the past year.

The PRESIDENT said there would be no harm in presenting the return, but it must be borne in mind that the year just closed had been quite an exceptional one, many expenses having been incurred which would not occur again.

LAW AND PARLIAMENTARY.

The report of this Committee included a letter from the Solicitor, narrating the progress which was being made in several matters entrusted to him. In several cases he was awaiting further evidence. Information was also contained in the report with regard to other cases of alleged infringement of the Pharmacy Acts, which had not been placed in the hands of the Solicitor. The case of a co-operative store dispensing medicines containing poisons had been brought under the notice of the Committee. The Committee recommended that the solicitor be instructed to obtain legal evidence of the infringement of the Act, and to report to the Committee. A report had been received from the Sub-Committee appointed to consider amendments to the Pharmacy Acts, enumerating certain suggested alterations which might be introduced into an amended Bill, if a favourable opportunity offered.

Mr. BOTTLE remarked that the report of the Sub-Committee was not quite so full as he could have wished, and he hoped the Committee would be reappointed by the new Council to continue its attention to the subject.

Mr. SCHACHT said the report of the Sub-Committee had been received, but not yet discussed or adopted by the Law and Parliamentary Committee, and he therefore thought the matter was hardly ripe for discussion.

Mr. SANDFORD concurred in this view.

Mr. HAMPSON thought the report of the Sub-Committee should be read.

Mr. ATKINS thought the report of the Sub-Committee should be read if the Sub-Committee had completed its work, but not otherwise.

Mr. SHAW did not see how the Council could consider a report which had not yet been discussed by the Parliamentary Committee to which it had been addressed.

The PRESIDENT after some further discussion, ruled that the report of the Sub-Committee should be read but not discussed, and it was read accordingly.

Mr. BOTTLE moved that the report be referred back to the Parliamentary Committee, with a request to report to the Council at its next meeting.

Mr. ATHERTON seconded and Mr. Betty supported the motion.

Mr. SCHACHT objected to the motion as out of order, inasmuch as the report of the Sub-Committee had not been properly presented by the Law and Parliamentary Committee.

Mr. HAMPSON was anxious that the work already done by the Sub-Committee should not be lost, and that he believed was all that was aimed at by Mr. Bottle's motion.

Mr. SANDFORD saw no necessity for a special resolution asking the Committee to continue their attention to the subject.

It was ultimately agreed that the Law and Parliamentary Committee be requested to continue the appointment of the Sub-Committee.

The report and recommendations of the Committee were then adopted.

The Secretary reported that the certificate presented to Mr. Colegrove on his passing the Minor Examination had been returned and was now in the possession of the Society; and also that Mr. Colegrove's name had been erased from the Register of Chemists and Druggists.

GENERAL PURPOSES.

This Committee had received the reports from the Professors on the class examinations at the end of the first five months' course.

Professor Redwood had reported that thirteen candidates took part in the examination, of whom five had obtained a sufficient percentage of marks to entitle them to recognition.

Professor Bentley had reported that seventeen students of his class had competed, of whom three had obtained a sufficient percentage of marks to entitle them to recognition.

The envelopes bearing the mottoes of the successful competitors had been opened by the Committee, and the names ascertained.

The Committee recommended that in accordance with the reports of the Professors the following awards should be made:—

CHEMISTRY AND PHARMACY.

Bronze Medal	George Frederick Gutheridge.
Certificate of Merit ..	Rawson Parke Francis.
" "	David Avison.
" "	George William Bullen.
" "	Henry Peirson.

BOTANY AND MATERIA MEDICA.

Bronze Medal	George Frederick Gutheridge.
Certificate of Merit...	Rawson Parke Francis.
" "	George William Bullen.

The Committee also recommended that the following grants be made for educational purposes to provincial Associations:—

£50 to the Bristol Pharmaceutical Association, for the purchase of books, including those enumerated in a list accompanying the application. The duplicate specimens of materia medica and of dried plants applied for, to be presented to the Association as far as this can be done without injury to the Society's Museum.

£5 to the Oldham Chemists and Druggists' Assistants and Apprentices' Association.

Mr. SCHACHT on behalf of the Bristol Association, thanked the Council for the grant which had been made and which he was sure would be well used. He would also remark that he had ascertained the proportion of registered persons in various towns, who were connected with the Society. In Manchester the proportion was sixteen per cent. of those on the register; In Sheffield eighteen per cent.; Leeds, nineteen per cent.; Hull, twenty-two per cent.; Liverpool, twenty-three per cent.; Bristol, 30·3 per cent.; London, 30·7 per cent. So that the difference between Bristol and London was only ·4 per cent.

The PRESIDENT said these figures were very remarkable as showing what a large proportion of the trade in London held aloof from the Society. It showed the necessity for some greater efforts being made in the metropolis, as well as other large towns, to enlist the sympathies of chemists and druggists.

Mr. BOTTLE remarked that the per-centage seemed to be greater in small towns than in large towns. In Dover, where there were but fourteen or fifteen chemists, the Society had about seven members.

"PATENT MEDICINES" CONTAINING SCHEDULED POISONS.

The Secretary read a communication from the Hull Chemists' Association enclosing a resolution calling attention to the fact that opium, solid and tincture, is being largely sold by unregistered persons, with a patent medicine stamp, and suggesting that the sale of all articles covered by a patent medicine stamp, containing any of the scheduled poisons, should be strictly confined to registered persons. The communication was referred to the Law and Parliamentary Committee.

THE BENEVOLENT FUND.

The SECRETARY read a letter he had received from a member of the trade, saying he was authorized by a friend to offer a donation of £100 to the Benevolent Fund, provided forty-nine other persons would contribute a like amount before the day fixed for the dinner in May next, or £50, if ninety-nine others would contribute a similar amount; it being understood in either case that the sums be contributed in individual names, and not by firms, and that no larger amount be presented under any one name.

PHARMACEUTICAL MEETING.

Wednesday, April 4, 1877.

MR. JOHN WILLIAMS, PRESIDENT, IN THE CHAIR.

The minutes of the previous meeting were read and confirmed.

The following donations to the library and museum were announced, and the thanks of the Society were awarded to the donors:—

Library.—Aiton's 'Hortus Kewensis,' 1789, 3 vols., from Mr. W. Pickard; 'Human Interests, Reflections, etc.,' two copies, from Mr. S. Sainsbury (Author); 'The Lias of Fenny Compton, Warwickshire,' from Mr. T. Beesley (Author); 'Calendar, 1877,' from the Pharmaceutical Society of Ireland.

Museum.—Fine Specimen of Calisaya Bark and Specimen of Mongumo Bark, from Mr. Chantre; very large Crystal of Thymol, from Messrs. Wright, Layman, and Umney; Specimen of Gum Arabic, from Mr. R. H. Parker, Barnstaple; Specimen of Pure Iodide of Potassium, and fine Crystals of Biphosphate of Sodium, from Messrs. Hopkin and Williams; Specimen of Australian Opium and Eucalyptus products, from Messrs. Hearon, Squire and Francis; Measures for Doses of Medicine, from Mr. Proctor; Specimen of Glass Wool, from Messrs. Corbyn and Co.

The CURATOR called attention to the sample of iodide of potassium, which he said was whiter than any he had ever seen before. It would be interesting to watch whether this whiteness was permanent. Three specimens had been given to the museum at different times as pure iodide of potassium and each had become coloured. The sample of gum illustrated the variety which had been met with in the market during the last few years, and which had the curious property of forming with water a mucilage that was gelatinous when concentrated, and glairy, like white of egg, when diluted.

Mr. GREENISH asked Mr. Holmes whether he had examined the specimen of gum arabic under the microscope to ascertain whether there was any cell tissue in it, and whether there was any structural difference between the mucilage formed by the present specimen and that formed by ordinary gum.

Mr. HOLMES replied that he had not examined microscopically the sample before the meeting. Hanbury ('Pharmacographia,' p. 210, note 3) mentioned that if the mucilage of this gum were exposed for some days to a temperature of 95° C., it afforded a solution of the usual character. He (Mr. Holmes) was not aware whether it had been examined chemically for the purpose of ascertaining whether it was a gummate of some other base than calcium and magnesium, or whether there was a chemical difference between it and ordinary gum arabic.

Mr. GREENISH said it would be very interesting if Mr. Holmes would examine it and ascertain whether there were any cell tissue and any remains of starch in it similar to those which could be detected in gum tragacanth which owed its origin to a chemical metamorphosis of the cell and its contents, and to the mucilage of which this bore some resemblance.

The PRESIDENT called attention to the beautiful specimen of so-called "glass wool," presented by Messrs. Corbyn and Co. It consisted of glass spun as fine as the ordinary fibre of wool. It was made in Germany, and was proposed for the filtration of very acid solutions, such as chromic acid, and other solutions of a very corrosive character. It was not altogether perfect as a filtering body, for, on account of the surface being highly extended, the alkaline property of the glass was very highly developed, and it was rather apt to decompose such bodies as hydrocyanic acid. He was sure that, as a specimen of spun glass, that before the meeting would be admired by every one.

Mr. NAYLOR said that the process of manufacture consisted in fusing Bohemian glass and, while in the fused condition drawing it out into threads and winding the threads round hot cylinders. He could confirm what had been said with reference to the utility of this substance as a filtering medium. It was extremely useful in filtering any strongly acid solutions and strongly alkaline solutions, and he had found it especially useful for albuminous solutions. If the wool were well washed with water before being used, it became much softer than it was previously, and formed a more compact filter. This substance had been brought before the Société de Pharmacie in Paris, as reported in the *Pharmaceutical Journal* for October 14th last.

In reply to the President,

Mr. Naylor added that he had tried a specimen with test paper after washing, and that it did not give any alkaline reaction.

The President said that the specimen of iodide of potassium had been made by his firm with a great deal of care and trouble. Pure iodide of potassium was of course perfectly neutral, and should contain no carbonate, sulphate, or iodate; it ought not to discolour by keeping, or when treated with an acid, such as tartaric or hydrochloric. It was, however, difficult to get all these qualities combined in one specimen. It would be interesting to ascertain how long the present specimen would keep white, but that, of course, was a point which could only be decided after the lapse of several years. This sample answered to every test for purity, with the exception of having a slight subiodous smell which rather suggested that there was still some impurity present. He should like also to call attention to the specimen of biphosphate of soda, or acid phosphate of soda. It crystallized with great beauty, and appeared to be a very permanent salt, whereas they knew the ordinary diphosphate of soda effloresced very readily, and had an alkaline reaction. This salt, the biphosphate, was distinguished by not precipitating phosphate of lime from a solution of chloride of calcium until it was neutralized by an alkali. It appeared to him probable that biphosphate of soda might be very usefully employed in medicine. When medical men administered a phosphate what they most required was the phosphoric acid. In making a compound syrup of the phosphates it was an advantage not to have an alkaline phosphate either of potash or of soda. He would suggest the use of this acid phosphate which would not precipitate the other ingredients used in the syrup.

Professor Redwood said he apprehended that the President did not at all contemplate the advisability or necessity of aiming at the great amount of purity which was possessed by the iodide of potassium he had brought under their notice.

The President: Oh, no. It is merely a chemical curiosity, prepared for strictly chemical purposes.

Professor Redwood stated that the amount of purity which the sample possessed would necessarily be purchased at a very high price. With reference to the phosphate of soda, possibly a somewhat similar consideration would arise as to the cost of obtaining it, though he did not apprehend that there would be the same increase of price in the production of a salt of that description, as there would be in the other case. In the ordinary phosphate of soda there were impurities that were admitted according to the Pharmacopœia tests, those impurities being connected with the methods which were adopted for the production of the salt in a cheap manner. He felt that there was a great deal of weight in what the President had stated with regard to the advantage of employing a phosphate of soda which was not alkaline like the ordinary phosphate.

Mr. Hancock exhibited a machine for compounding powders. He demonstrated its use by preparing, in the presence of the audience, a powder consisting of rhubarb and magnesia. He said that the apparatus consisted simply of a slightly conical cylinder into which might be fitted any one of the various sieves which were on the table, the meshes of which varied from thirty up to ninety meshes to the square inch. A brush was fitted to a spindle and placed in the interior of the machine, and a lid was then put on the top; the brush being caused to rotate, mixed together the ingredients of the powder, and at the same time drove them through the sieve.

Professor Redwood said that he had no doubt that the apparatus would be a very useful, convenient and efficient one for preparing many of the powders which were used in pharmacy. It would contribute to the carrying out of one of the three operations which were indicated in the Pharmacopœia for the production of powders, those operations being the mixing of the ingredients, the passing them through the sieve, and then the rubbing them lightly in a mortar. The importance of those three distinct operations was not always sufficiently appreciated. He must admit that there was a defect in the directions given in the Pharmacopœia with regard to passing the ingredients through a sieve. The Pharmacopœia mentioned a "fine" sieve, but there was no indication as to what a fine sieve signified. That was an omission that would have to be remedied some day or other, because the number of meshes to the square inch might be mentioned.

Mr. Greenish thought that the apparatus would be a very useful one for the chemist, but in its present form it had the defect of having a sufficient space between the sieve and the body of the apparatus to allow the passage of particles larger than would go through the meshes of the sieve.

Mr. Hancock said that he did not think that the defect alluded to by Mr. Greenish would be of any consequence, for the space would be speedily filled up by the powder itself. The machine might be made more accurate, but the one object had been to make it cheaply.

Professor Attfield then read a paper on

Medicine Measures.

BY MR. BARNARD S. PROCTOR.

The paper is printed on p. 809.

The President in inviting a discussion remarked that the idea of the author was a most ingenious one, and, whether pharmacists adopted it or not, they would be struck with the fact that it attempted to meet a great difficulty.

Mr. Greenish said it would be recollected that a discussion on this subject took place in the *Pharmaceutical Journal* a few months ago, and the universal opinion then expressed was that there was a very great difference in the size of the teaspoons and tablespoons in general use. His own opinion was that the necessary change must commence with medical men. The physician in writing his prescription ought to order medicines to be taken by the ounce or half-ounce or drachm, as the case might be, instead of by the spoonful, the words "by measure" being added within brackets. He could not clearly see his way out of the difficulty by the use of the measures which Mr. Proctor had recommended. Medicines had to be taken in doses of so many different sizes that chemists would want no end of these measures. He believed that a glass measure, marked with doses varying from a teaspoon to a wine glass, would eventually have to be used. The use of spoons as measures ought to be abolished.

Mr. Bland said that the subject was surrounded with very considerable difficulty. He agreed with Mr. Greenish that so long as the majority of medical men prescribed medicines by the teaspoonful and the tablespoonful, pharmacists would be obliged so to label their medicines when sent out. Many people thought that they could escape the difficulty by using graduated bottles, but he believed that that was almost as great an error as relying upon teaspoons and tablespoons. He had examined a vast number of graduated bottles, and had found that the spaces varied from 38 minims up to more than 80 when they were intended to be all of the same size. Considering the manner in which graduated bottles were manufactured, it was very natural that there should be this discrepancy. He believed that the great expense of furnishing Mr. Proctor's measures gratuitously, as was proposed in the paper, would very much tend to hinder the introduction of such measures. For instance, a person would come and ask for a couple of pennyworth of spirit of nitre, and request to be informed how it was to be taken. Was the chemist to make the customer a present of a measure in such a case? Things of this sort were continually happening in retail shops, though he supposed that they did not occur so frequently among the *dii majores* of the West End. In poor neighbourhoods customers would be neither willing nor able to pay for the measures.

Mr. LONG said that he certainly did not think that Mr. Proctor's plan was at all likely to succeed. In the first place, he did not see how they were to get absolute accuracy in the measures any more than in the spoons. In the second place, thick mixtures would stick to the measure and a good deal would be lost, and nine people out of ten would slop the mixture down the side. The whole question, it seemed to be assumed, was one of cheapness. He did not think that theirs was a vocation into which the question of cheapness ought to enter at all. If people were ill they wanted medicine, and the very persons who would quibble about the price of a bottle of medicine would, if they belonged to the upper classes of society, lavish large sums of money on their exteriors, and if they were in the humbler class, though they would grumble about paying a trifle for their medicine, they would willingly go across the road and spend the same amount in gin. He, therefore, held that chemists ought to introduce the best appliances which could be got for measuring medicines, and that the consideration of cheapness ought not to enter at all. He believed that graduated bottles ought to be done away with. There was already too much complication in their business, and they had bottles graduated to all imaginable doses. They ought to insist that those who could afford measuring glasses should use them. Doctors had no right to prescribe mixtures in a concentrated form, to be diluted with water by the patient. A serious accident had occurred in Edinburgh through a lady taking an overdose of liquor strychniæ, which had been prescribed for her in five-drop doses. The practice of prescribing medicines in the concentrated form arose from a desire for economy. But why should not the druggist have his chance of getting a living with the rest of the world? What with co-operative stores and parsimonious doctors, he was at a great disadvantage in this respect.

MR. BLAND said that if he had to dispense a very powerful medicine he carefully graduated the bottle with diamond marks, and then attached to the outside of the bottle a strip of paper with marks corresponding to the diamond marks to indicate the separate doses.

Mr. MARTINDALE considered that it would be better to stamp the measures proposed by Mr. Proctor, "one drachm," "half-ounce," and so on, rather than "one teaspoonful," "one tablespoonful," etc. Spoons had been much increased in size of late years, and he (Mr. Martindale) had accordingly suggested, as a remedy for the present state of uncertainty, that a teaspoonful should be regarded as $1\frac{1}{2}$ drachms, and a tablespoonful as 6 drachms. No doubt even the moderately poor could afford to provide themselves with measuring glasses; but perhaps a third of the medicine taken in London was supplied from the out-patients' department of the hospitals, to persons who were too poor to buy measures of any kind. In France it was understood that a tablespoon contained 20 grammes of water, equal to about 5 drachms and 40 minims, and a teaspoon 5 grammes, equal to about 85 minims. He had pointed out to Mr. Proctor the desirability of providing the measure with a spout, but Mr. Proctor had told him that the spout would greatly increase the cost of the measure and cause inaccuracy in the size. While on this subject, he would ask Professor Redwood what chance there was of introducing in a new edition of the Pharmacopœia the metric system. In doing so there ought to be some fluid measure introduced, as well as measure by weight, and he hoped that, if the metric system were adopted, it would not be in the form introduced into the German Pharmacopœia, which consisted in casting the whole Pharmacopœia into parts by weight.

Professor REDWOOD said that a reprint of the Pharmacopœia had appeared within the last two months, and although it contained no material alteration, yet the fact of many thousand copies having been printed would stand in the way of a new edition coming out shortly. Independently of that difficulty, there were probably others quite as influential. As a rule he thought the medical men of this country were satisfied with the work in its present form, and they said that it contained, in an intelligible form, a fair representation of the medicines which they required to prescribe. There seemed to be a greater indisposition towards a new edition than there was four or five years ago. Passing to the subject before the meeting, he must confess that he had been unable to understand the advantage which Mr. Proctor's method possessed, in any respect, over the use of graduated measuring glasses which had already been adopted to a great extent. The graduated measuring glass would be an individual standing in the place of a little regiment of measures which would be introduced under Mr. Proctor's system. In households where medicines were constantly being delivered the measures would accumulate to such an extent that they would be a source of much confusion, though they might form very nice toys for the children. The labels would very soon become obsolete, and there would be a danger of the larger measures being used in the place of the smaller ones. On the whole it appeared to him that graduated glass measures, having the different spoonfuls indicated on one side and the quantity in ounces indicated on the other, would be the safest and most convenient appliance for the measurement of doses.

Mr. PLOWMAN said that practical experience enabled him to appreciate the difficulty which Mr. Martindale had referred to in connection with hospital practice. He (Mr. Plowman) thought that Mr. Proctor's suggestion must be laid aside entirely as regarded hospital outpatients. A couple of gross of Mr. Proctor's measures would have to be given away daily, on an average, at a hospital of fair size. The suggestion of Mr. Martindale that the tablespoon should be reckoned as six drachms was a very good one, if that measure was correct. He should like to ask that gentleman whether he had ascertained from actual measurement that the modern tablespoon contained six drachms. This suggestion of Mr. Martindale was the only one of those which he (Mr. Plowman) had heard that evening which was at all likely to meet the difficulty of hospital out-patients.

Mr. MARTINDALE, in answer to the last speaker, said that he had ascertained, from actual observations, that six drachms was the average capacity of tablespoons. He had had his observation in this respect confirmed by that of an ironmonger. When he (Mr. Martindale) was connected with a hospital he found that a bottle of mixture intended to last a week would sometimes be exhausted in four or five days. The way in which he partially got over the difficulty was to have printed on the labels "small tablespoonfuls." In the hospital with which he was connected the average dose for an adult was one ounce, and that was always taken to be two tablespoonfuls.

Mr. HILLS said that he had never found any difficulty with graduated bottles. If they were inaccurate let them be returned to the makers. He had always recommended to medical men that they should never make the doses less than a tablespoonful. In order to encourage the use of measuring glasses among medicine takers, he had made it a practice to supply those articles at as low a price as possible.

Mr. LONG said, that he had sometimes given a $\frac{1}{2}$ oz. or 1 oz. bottle to poor people to be used as a measure. He had found great difficulty with graduated bottles.

The PRESIDENT said that he thought that the conclusion at which they must all arrive was that a graduated measuring glass was the most advisable thing for public use in the present condition of affairs. One point which had come out in the discussion was that medical men acted very foolishly, or even very wrongly, in prescribing medicines in a concentrated form for the general public. There was no doubt that the public gained a little economy by such a practice, but they did so at the risk of their lives; and whether it was worth while to take such a risk for so trifling an advantage, was a question which ought to be brought very strongly before not only the public, but the medical profession. No doubt the public safety was best cared for in the old days of 2 oz. draughts, or when, as a rule, mixtures containing dilute medicines were prescribed and a little more or less taken in the dose would make no practical difference. A very concentrated medicine involved the patient in great risk.

Mr. HOLMES said he thought that the chemists were somewhat to blame for the introduction of concentrated medicines, because mixtures were generally charged for according to the size of the bottle. If they were charged for according to the number of doses contained in the bottle, a very great difference would be made by medical men in the size of the doses which they ordered.

Mr. GREENISH said that the theory of charging by the dose was a very pretty one, but it was utterly impracticable.

Mr. LONG said that the practice was very general.

Mr. M. CARTEIGHE said that if the charge were not based upon the number of doses he did not know on what basis it could be put. As to the size of the dose, the primary responsibility rested on the prescriber. In these railway times everything was wanted in the most portable form. Physicians were affected by the times, and they sometimes prescribed doses in a form which in his judgment as an individual and a pharmaceutist was distinctly dangerous. The practice of ordering concentrated doses of potent medicines was a subject of serious importance to the physician. It was a source of anxiety to the pharmaceutist, and fraught with considerable danger to the public.

GLYCERINUM TRAGACANTHÆ.

MR. GREENISH said that at the Pharmaceutical Conference at Glasgow there was a great deal of discussion upon the use of an excipient of glycerine and tragacanth for pill masses. Mr. Thresh, who was present at that conference, had since gone very fully into the subject, and had published a paper in the *Pharmaceutical Journal* of last week. He had come to the conclusion that tragacanth with glycerine was not at all adapted for the pill masses of the Pharmacopœia. On this point, he (Mr. Greenish) had no experience. But Mr. Thresh, in his concluding paragraph, stated that that compound was really not so good for general purposes as many other excipients. With this statement he (Mr. Greenish) totally disagreed. He believed it to be one of the best excipients which they could possibly have on the dispensing counter. The proportion which he used was 1 drachm by weight of tragacanth and 8 drachms by measure of glycerine. The ingredients were rubbed in a mortar and allowed to stand a day or two, to gelatinize. This excipient was specially useful for quinine, and exceedingly useful for valerianate of zinc. It was also specially good for sulphate of iron and aloes. It had also the advantage that there was no colour attaching to it, as for instance, it was desirable to have quinine pills as white as possible. Confection of roses had a certain amount of colour. Pills made up with the tragacanth and glycerine did not become at all damp.

LECTURE BY PROFESSOR REDWOOD ON SPECTRUM ANALYSIS.

The PRESIDENT announced that on Wednesday, the 2nd May, Professor Redwood would deliver a lecture on "Spectrum Analysis," illustrated by the Society's new apparatus.

Proceedings of Scientific Societies.

CHEMICAL SOCIETY.

Thursday, March 29, 1877. Professor Abel, F.R.S., President, in the chair.

ANNIVERSARY MEETING.

At this meeting the President delivered his annual address, giving an account of the progress and present state of the society, from which it appears that the increase during the past year has only been thirty-five, making the total number of Fellows 919. The losses by death have been sixteen: Messrs. T. Charlesworth, F. C. Devigne, H. Deacon, Paul de la Rue, David Forbes, A. Harvey, J. Hearder, F. H. Hobler, A. S. Hobson, C. Lambert, L. A. Lucas, M. Lichtenstein, G. Parry, Alfred Smee, F. Smith and T. H. Wyndham, besides one foreign member, M. Balard, the distinguished discoverer of bromine. Seven foreign members have been elected, viz.: Professors Bäyer, Butlerow, Cooke, Friedel, Heintz and Thomsen. The number of communications brought before the society last year was seventy, being more than in any previous year, besides two lectures, the one "On Certain Methods of Physico-Chemical Research," by Professor Andrews, and the other, "On the Theory of the Bunsen Flame," by Professor Thorpe. The fund for the promotion of chemical research has made very satisfactory progress and now amounts to more than £3000, including the munificent donation of £1000 by Dr. Longstaff and a like amount given by the Goldsmiths' Company. The state of the ordinary income of the society, however, is much less favourable, owing to the small increase in the number of Fellows as compared with former years, being less than half what it was last year, and less also than in any of the four previous years. There is but little doubt that the cause of this very serious falling off is to be ascribed not only to the blackballing which has been taking place for some time past, but to the effect which certain instances of manifestly unjust exclusion by this means has had in deterring candidates from offering themselves for election. This system of blackballing is pursued by a small section of those Fellows who regularly attend the meetings, as is evident from the fact that the number of black balls does not exceed eight or nine. As, however, one-fourth negative balls suffices to exclude a candidate, this ensures the blackballing of the candidate unless the attendance of Fellows is numerous at the commencement of the meeting. It was to be hoped, however, that the injurious effects of their mode of action, which is most seriously imperilling the future prosperity of the society, would induce them to give the matter their serious consideration. The President then gave an account of the negotiations which had taken place between the Council and the Committee for Organization amongst Professional Chemists, which had since developed into the "Institute of Professional Chemists," and noticed the alteration which had been made in the Fellows' certificate for election, and the reasons which had induced the Council to propose the alterations in the bye-laws which were to be submitted to them that evening.

The Treasurer then read his report; Messrs. Carteighe, Friswell and Nicholson being Auditors.

Mr. E. Neison said he would like to draw the attention of the Fellows to two or three matters before the adoption of the President's report was moved, and then pointed out: 1. That although the general index to the society's journal had cost a large sum, £282, comparatively few copies had been sold. He thought it would be advisable to distribute the index gratuitously to the Fellows. 2. He stated that the laboratory was very insufficiently supplied with apparatus and chemicals, and suggested that when the society granted money to chemists for assisting them in conducting original research, they might at the same time place the laboratory at their disposal.

3. That a very long time, three to four months or more, elapsed between the reading of a paper at one of the society's meetings and its appearance in the journal, and concluded with some remarks on the blackballing which had recently taken place in the society.

Professor Williamson remarked that it was most important that some appropriate occasion should be offered for the discussion of various matters affecting the welfare of the society, and was very glad that they now had an opportunity of talking over this matter of the blackballing together. He was very jealous of the privilege, or rather duty, of the Fellows of excluding those candidates who were not properly qualified, but at the same time this function should be exercised with the greatest discretion. No doubt this action had been taken on some principle, but it was a principle which he did not understand, and if instead of producing the effect they desired, it had produced others of an unexpected and perhaps disastrous character, he hoped those members who had exercised this privilege would reconsider their mode of action, which, if continued, would produce very serious injury to the well-being of the society.

Mr. Kingzett made some remarks on the subject of blackballing, and also complained that a paper, by Dr. Hake and himself, read before the society in January last, had been returned to him by the Committee of Publication, with suggestions that he should make certain alterations in it before it was published in the society's journal. [He said if it were true that the blackballing, of which complaint had been made from the chair, was the work of less than ten Fellows of the society, and if it were right to characterize their action as "unjust and indiscriminate," it was much to be regretted that the said Fellows could not be expelled from the society; but in his opinion it was rather an injustice to characterize in this way the exercise of a privilege appertaining to the Fellows of the society. Besides, as a matter of fact, he remembered one occasion when there was a largely attended meeting of the society, and then three out of five candidates for election were blackballed, a result which signified that at least twenty men, not eight or nine only, had taken part in the blackballing. He considered it was unjustifiable that in the President's address the action of any Fellows of the society in the exercise of their privilege should be commented upon in any way whatever. He reminded the meeting that at one time the influx of unqualified men into the society had become so notorious, that a so-called doctor who sold bogus degrees would have been elected, had it not been for the fact that the Fellows of the society were roused to a sense of duty. It could not be admitted that there had been anything unjust or indiscriminate in the blackballing, and it was an unconstitutional act on the part of the council who prepared the report so to speak of it. He did not defend every case of blackballing, but he accepted it as the result of a spontaneous evolution of conscience. As regarded the journal of the society, Mr. Kingzett pointed out that in 1876, between the nominal date of publication and the time of delivery to the Fellows, there was an average interval of forty days. Then again, the abstracts were not what they should be; for instance, taking the last number of the journal (March) there was given in it an abstract of a paper by M. Hardy on Jaborandi which was published before January, 1876, in which month an abstract of it was printed in the *Pharmaceutical Journal*. Further, it was scarcely fair to authors that their papers, read before the Society, should be sacrificed to the interests of others; as it was, three or four months now elapsed before authors' papers were printed. He now came to the most important matter. The Fellows would remember that during last January, Dr. Hake and he had read a paper before the society which elicited at the time some discussion. Since then the paper had been returned to the speaker with various undermarkings in blue pencil, and queries placed against conclusions drawn from experiment! Moreover he had been requested to alter the title, abbreviate the paper and pledge himself to conclusions which he could not entertain and which could only be put forward by reason of a non-comprehension of the meanings of experiments and facts. Dr. Hake and he had absolutely refused to make a single alteration regarding their paper, and if the society would not publish it as it stood they (the authors) would publish it elsewhere. The speaker went on to say he recognized one method of criticism only in science, viz., the method of experiment, and he invited the gentlemen who had abused his paper to resort to that method. Finally, he wished to ask a few questions. By what authority did the Committee of Publication exist? Why is its composition a constant? Who attended the meetings? and, How did it perform its functions?]

Dr. Thudichum made a similar complaint. Several of his communications had been treated in the same way. He had addressed a solemn letter to the Council on the subject, but had received no reply.

Dr. Odling said that the management of the affairs of the society was entrusted to the Council by the Fellows. Some of the papers were undoubtedly delayed, but only those papers which the Publication Committee did not at first see their way to recommend for publication, and which were referred to be specially reported on. Some sort of censorship must be exercised: it would be very unreasonable to ask them to undertake to publish indiscriminately every paper which might be presented. With regard to the blackballing he quite agreed with Dr. Williamson that it was most important that the privilege should be exercised with the greatest discretion, but in this case it was evident that a small section of the society, a minority of eight or nine members, who regularly attended the meetings, were thwarting the wishes of the majority, since one black ball in four was sufficient to reject a candidate.

Mr. E. Riley thought it would be far better to adjourn this discussion and proceed with the business of the evening: he therefore begged to second the motion that the Report of the President be received.

It was moved by Mr. Kingzett, as an amendment, and seconded by Dr. Thudichum, that the words "unjust" and "indiscriminate" in the report, as applied to the blackballing, be omitted.

The amendment was then put by the President, but only twelve members voted for it out of the crowded meeting; the original motion was put and carried.

The election of officers and Council for the ensuing year was then proceeded with, Messrs. Riley, Carteighe and Neison being appointed scrutators. The following gentlemen were elected:—President, Dr. J. H. Gladstone; Vice-Presidents, Messrs. F. A. Abel, Sir B. C. Brodie, Warren de la Rue, E. Frankland, A. W. Hofmann, W. Odling, L. Playfair, A. W. Williamson, T. Andrews, W. Crookes, F. Field, J. H. Gilbert, H. E. Roscoe, J. Stenhouse; Secretaries, Messrs. W. H. Perkin and H. E. Armstrong; Foreign Secretary, Mr. H. Müller; Treasurer, Mr. W. J. Russell. The other members of Council are, Messrs. J. Attfield, Lowthian Bell, A. H. Church, C. E. Groves, W. N. Hartley, C. W. Heaton, T. H. Hills, David Howard, G. Matthey, J. A. Phillips, R. V. Tuson and C. R. A. Wright.

A vote of thanks to the retiring President, Professor Abel, which was received with acclamation, was proposed by Professor Williamson and seconded by Dr. Warren de la Rue. There were also votes of thanks to the officers and Council, proposed by Mr. Carteighe and seconded by Mr. Tennant; to Mr. Watts and the Abstractors by Dr. Odling and Mr. Crookes, and to the Auditors by Dr. Russell and Dr. Paul.

Professor Abel then dissolved the meeting, and resolved it into a special general meeting, to consider some alterations in the bye-laws, when the new President, Dr. Gladstone, took the chair.

Mr. Neison proposed some verbal alterations. A discussion arose as to these resolutions being brought forward without notice, Mr. Neison ultimately agreeing to postpone the matter until the next annual meeting.

The following alterations in the bye-laws, proposed by the Council, were then put to the meeting and carried unanimously:—

In paragraph II. of the bye-law relating to Associates, (*a*) The words at the commencement of the second paragraph to be "Associates shall pay an annual subscription of one pound." (*b*) The following words to be added at the termination of the second paragraph: "But they shall have the option of paying an annual subscription of thirty shillings in place of one pound, for which subscription they shall be entitled to a copy of the society's journal, in addition to the ordinary privileges of Fellows, with the exceptions hereinbefore specified."

Also the new form of obligation to be signed by Fellows on their admission (the words in italics being the additions to the old form):—

"I, the undersigned, do hereby engage that I will endeavour to promote the interests and welfare of the Chemical Society; *that I will* observe its laws, and *to the utmost of my power maintain* its dignity, as long as I shall continue a Fellow thereof."

The meeting was then adjourned until Thursday, April 5.

SOCIETY OF ARTS.

Certain Relations between Plants and Insects.*

BY SIR JOHN LUBBOCK.

(*Continued from p.* 804.)

The last of the five points to which I called your attention was the eye-spots. In some cases spots may serve for concealment, by resembling the marks on dead leaves. In *Deilephila hippophæ*, which feeds on the hippophæ, or sea buckthorn, a very grey green plant; the caterpillar, also, is a very similar grey-green, and has, when full grown, a single red spot on each side, which, as Weissman suggests at first sight much resembles in colour and size one of the berries of the hippophæ, which, moreover, are present, though not ripe, at the same period of the year. Again, in *Chærocampa tersa*, there is an eye-spot on each segment, which mimics the flower of the plant on which it feeds (*Spermacoce hyssopifolia*). White spots, in some cases, also resemble the spots of light which penetrates the foliage. In other cases, however, and at any rate in our elephant hawk-moth, the eye-spots certainly render the insect more conspicuous. Now in some cases, as Wallace has pointed out, this is an advantage rather than a drawback. Suppose that from the nature of its food, or any other cause, as for instance from being covered with hair, a small green caterpillar was very bitter, or in any way disagreeable or dangerous as food, still in the number of small green caterpillars which birds love, it would be continually swallowed by mistake. If, on the other hand, it had a conspicuous and peculiar colour, its evil taste would serve to protect it, because the birds would soon recognize and avoid it, as Weir and others have proved experimentally. We have a striking case of this among the hawk-moths in *Deilephila euphorbiæ*, which feeding on the Euphorbia with its bitter milky juice, is very distasteful to birds, and is thus actually protected by its bold and striking colours. The spots on our elephant hawk-moth caterpillar do not admit of this explanation, because the insect is quite good to eat—I mean for birds; we must, therefore, if possible, account for them in some other way. There can, however, I think be little doubt that Weissmann is right when he suggests that they actually protect the caterpillar by frightening its foes.

Everyone must have observed that these large caterpillars have a sort of uncanny, poisonous appearance; that they suggest a small thick snake or other evil beast, and the eyes do much to increase the deception. Moreover, the segment on which they are placed is swollen, and the insect when in danger has the habit of retracting its head and front segments, which gives it an additional resemblance to some small reptile. That small birds are, as a matter of fact, afraid of these caterpillars (which, however, I need not say are in reality altogether harmless) Weissmann has proved by actual experiment. He put a caterpillar in a tray in which he was accustomed to place seed for birds. Soon a small flock of sparrows and other small birds assembled to feed as usual. One of them lit on the edge of this tray, and was just going to hop in, when she spied the caterpillar. Immediately she began bobbing her head up and down, but was afraid to go nearer. Another joined her, and then another, until at last there was a little company of ten or twelve birds, all looking on in astonishment, but not one ventured into the tray, while one which lit in it unsuspecting, beat a hasty retreat in evident alarm as soon as she perceived the caterpillar. After watching for some time, Weissmann removed the caterpillar, when the birds soon attacked the seeds.

Other caterpillars also probably, of nearly allied species, are protected by their curious resemblance to spotted snakes.

There are many—very many—other points connected with the colouring of sphinx caterpillars, to which I might refer if time permitted. I will only allude to two. The peculiar hues of the death's-head hawk-moth caterpillar, which feeds on the potato, and unites so beautifully the brown of the earth, the yellow and green of the leaves, and the blue of the flowers, that, in spite of its size, it can scarcely be perceived unless the eye be focussed exactly upon it. The other is the anceryx. The caterpillars of this genus differ in style of colouring from all other sphinx larvæ, having longitudinal bands of brown and green. Why is this? Their *habitat* is different. They feed on the leaves of the pinaster, and their peculiar colouring offers a general similarity to the brown twigs and narrow green leaves of a conifer. There are not many species of lepidoptera which feed on the pine, but there are a few, and I have here diagrams of two, *Achatia spreta* and *Dendrobinus pini*, both of which, as you will see, have a very analogous style of colouring, while the latter has also tufts of bluish green hair which singularly mimic the leaves of the pine. I have added also the larvæ of a species of saw-fly (one of the hymenoptera), which also attacks the pine, and you will see that here also the colouring is curiously similar (*Lophyrus socia*).

But, as Wiessmann points out, we may learn another very interesting lesson from these caterpillars. They leave the egg, as we have seen, a plain green, like so many other caterpillars, and gradually acquire a succession of markings, the utility of which I have just attempted to explain. The young larva, in fact, represents an old form, and the species in the lapse of ages has gone through the stage which each individual now passes through in a few weeks. Thus the caterpillar of *Chærocampa porcellus*, the small elephant hawk-moth, a species very nearly allied to *Ch. elpenor*, passes through almost exactly the same stages as that of *Ch. elpenor*. But it leaves the egg with a subdorsal line. No one can doubt, however, that there was a time when the new-born caterpillars of *Ch. porcellus* were plain green, like those of *Ch. elpenor*. In this respect, then, *Ch. porcellus* is a newer specific form than *Ch. elpenor*. Again, if we compare the mature caterpillars of *Chærocampa* we shall find that there are some forms, such as *Ch. myron* and *Ch. chœrilus* which never develope eye-spots, but correspond to the second stage of *Ch. elpenor*. Here then we seem to have a species still in the stage which *Ch. elpenor* must have passed through long ago.

The genus Deilephila, of which we have in England

* From the *Journal of the Society of Arts*, February 23, 1877.

three species—the euphorbia hawk-moth, the galium hawk-moth, and the rayed hawk-moth, is also very instructive. The caterpillar of the euphorbia hawk-moth begins life of a clear green colour, without a trace of the subsequent markings. After the first moult, however, it has a number of black patches, a white line, and a series of white dots, and has, therefore, at one bound, acquired characters, which in *Ch. elpenor*, as we have seen, were only very gradually assumed. In the third stage the line has disappeared, leaving the white spots. In the fourth the caterpillars have become very variable, but are generally much darker than before, and have a number of white dots under the spots. In the fifth stage there is a second row of white spots under the first. The caterpillars not being good to eat, there is, as has been already pointed out, no need for, nor attempt at, concealment. Now, if we compare the mature caterpillars of other species of the genus, we shall find that they represent phases in the development of *D. euphorbiæ*. *D. hippophaæ* for instance, even when full grown, is a plain green, with only a trace of the line, and corresponds, therefore, with a very early stage of *D. euphorbiæ; D. zygophylli*, of South Russia, has the line, and represents the second stage of *D. euphorbiæ;* another Deiliphila has the line and row of spots, and the third stage; lastly, *D. vespertilio* and *D. galii* have progressed further, and lost the longitudinal line, but they never acquire the second row of spots which characterize the last stage of *D. euphorbiæ*.

The larvæ of insects teach us, indeed, many instructive lessons. It would be a great mistake to regard them as merely preparatory stages in the development of the perfect insect. They are much more than this, for the external circumstances act on the larvæ as well as on the perfect insect, and both, therefore, are liable to adaptation. In fact, the modifications which insect larvæ undergo may be divided into two kinds—developmental, or those which tend to approximation to the mature form; and adaptational or adaptive—those which tend to suit it to its own mode of life.

It is a remarkable fact, and except on those principles with which the name of our great countryman, Mr. Darwin, are justly united, I do not see how it can be accounted for, that the forms of larvæ do not depend on that of the mature insect. In these diagrams, for instance, are represented some very familiar larvæ, and the very dissimilar perfect forms which they ultimately assume. In other cases similar, or comparatively similar, perfect insects have very dissimilar larvæ. Indeed a classification of insects founded on larvæ would be quite different from that founded on the perfect insects. The *Hymenoptera*, for instance, which, so far as the perfect insects are concerned, form a very homogeneous group, would be divided into two—or rather one portion of them, namely, the saw-flies, would be united to the butterflies and moths. Now, why do the larvæ of saw-flies differ from those of other *Hymenoptera* and resemble those of butterflies and moths? It is because their habits differ from those of other *Hymenoptera*, and they feed on leaves like ordinary caterpillars.

From this point of view the transformations of the genus Sitaris, which has been very carefully investigated by M. Fabre, are peculiarly interesting.

(*To be continued.*)

Parliamentary and Law Proceedings.

Death from Chloral Hydrate.

On Saturday, March 31, Dr. Elliot, city coroner, held an inquest on the body of George Barling, aged forty-two years.

Catherine Brown, who had been nurse to the deceased for about nine months, said deceased had been in the habit of taking chloral hydrate every night when he could get it since witness went to attend on him, and sometimes he ate nothing for three or four days together, when he took mostly whiskey and chloral hydrate. Deceased always took the chloral hydrate himself and he would not allow anybody to see him taking it or in what quantity. About two months ago he asked witness to get for him 160 grains of chloral hydrate, but she refused, as deceased's wife, who often cautioned him not to take the chloral hydrate, desired her not to go. When she refused deceased said, "Oh, it will do no harm, I am used to taking it." Witness still refused to go, and he went out himself, and came back in about an hour and a half.

Twenty-three bottles were produced, only one of which had contained whiskey, all the others having been used for chloral hydrate, chloroform water, etc., but of the twenty-three two only were labelled, the first being from N. Taylor and labelled "Hydrate of chloral, 30 grs.," and the other from M. H. Pattinson and labelled "Solution of chloral: one tablespoonful contains ten grains of chloral."

Dr. Carlyle said that the bottle which was shown him that had contained chloral hydrate, and found in the bed of the deceased, was a six oz. bottle, but most of the others were four oz. bottles.

Hugh Jones, nineteen years of age, said he was an assistant druggist with Mr. N. Taylor. He had been three years in the trade altogether, but only two months with his present employer. He first saw deceased about a fortnight ago, when he came into the Abbey Street shop, and asked for 120 grains of chloral hydrate and four ounces of chloroform water. He asked Mr. Taylor, who was in the shop at the time, if he should supply him with it, and Mr. Taylor told him to give him 60 grains. Witness was labelling the bottle, but deceased prevented him, as he said it was for himself. He did not explain to deceased that he had given him 60 grains instead of 120. A jurymen: Of course he would know by the price that you only gave him 60 grains? Witness: No; I charged him the full amount. Deceased gave no prescription. The last time witness saw deceased was on Thursday, about five o'clock, the night before his death. He came into the shop and asked for two bottles of chloral hydrate, containing 150 grains each. Witness inquired of him why he wanted so much, and deceased said his wife was taking it also. He served him with 130 grains in two bottles, 65 grains in each, and four ounces of chloroform water. He labelled them both "Chloral—poison," but deceased pulled the labels off and said, "It is no use you labelling them; I know what it is too well." In answer to the Coroner, witness stated that it was on the representation that deceased wanted it for his wife that he gave him such a large quantity.

The Coroner expressed his surprise that this large quantity should have been supplied to deceased, and turning to witness he said: I want to impress upon you that this is not the way to dispense medicines, especially poisons. You must remember what it is that you are dealing in. It is a very frightful thing to have youths of your age dealing in these deadly poisons for the sake of a few pence, handing them out with as much freedom as if you were only selling turnip seed. A man asking for such a quantity ought to have put any person on his guard—300 grains!—and especially you who had read about chloral hydrate, and knew what chloral hydrate was.

A juryman said that the Coroner's remarks ought to have some effect, but he was of opinion that the blame rested with the master, and the foreman hoped that what had been said would be brought under the notice of other assistants, and that it would be a caution to them also.

The Coroner said that the law was inadequate to put a stop to cases of this kind. He mentioned this because it was not the first nor the second of these cases he had had, and it was not six months since he had held an inquest under exactly similar circumstances. The law would require to be amended, and he had taken steps to bring that about immediately after the last inquest in September, but nothing as yet had been done, and at present they had no power to prevent this being repeated to-morrow. He hoped that before long steps would be taken to render such things entirely impossible. This was not like an ordinary mistake which might be made by a druggist in dispensing medicine, but a person handing out freely large quantities of a most deadly agent.

A juryman asked the Coroner if there was not an examination to pass before a person could deal in drugs? Dr. Hair said that there was before he could deal, but he could dispense under an experienced chemist and druggist.

A juryman (to witness): Was there any qualified person in the shop when you dispensed this chloral?—Witness: No.

Witness in answer to other questions put by the jury, stated that Mr. Taylor had three shops in which were assistants, but Mr. Taylor was the only qualified person, as the assistants had not passed their examination.

A juryman asked if it would be a breach of the law for Mr. Taylor to have three shops, and he himself be the only qualified person to attend to them. Mr. Taylor could not be in three places at one time.—Dr. Hair said there was no law regulating the sale of chloral, because it was not included in the list of poisons.

Dr. Carlyle said that, in conjunction with Dr. Hair and Dr. Walker, he made a *post-mortem* examination of the body, and after reading the report which he had made, he said that their opinion was that death resulted from fatal fainting or syncope affecting the heart, which was loaded with fat and so feeble that chloral hydrate would act more powerfully on that account, and had so paralysed the heart as to cause death.

The inquiry was then adjourned until half-past ten o'clock on Monday morning.

Mr. Taylor was then sworn. He said he was a duly qualified druggist under the Pharmacy Act, and had been so since 1869. He had three shops; one in Botchergate, one in Abbey Street, and one in Castle Street. In the Botchergate and Castle Street shops he had in each an assistant and an apprentice; but he himself attended chiefly to the Abbey Street shop. He had also an assistant who was not stationed at any particular shop, but attended to any of the three when required. His assistants had all passed their Preliminary examination but not the Modified examination.

The Coroner explained that the Preliminary examination had nothing to do with their drug knowledge. It was merely something that they must go through before they commenced to learn their business.

In answer to a juror, Mr Taylor said he was perfectly acquainted with the Act—he had not gone into the business ignorantly—and according to it it did not matter whether they were qualified assistants or not. The Act merely stated that they could not carry on business for themselves. Even supposing he had qualified assistants in his shops that would not alter the state of things if anything occurred, as he himself was the responsible party. He could carry on a dozen shops if he wished, and not have a qualified assistant in one of them. He had no doubt but that his assistants were able to pass for qualified assistants, but they did not push for it.

The Coroner said that what they wanted to impress upon Mr. Taylor was that although chloral was not down in the list of poisons that fact should not weigh with him at all. A man's conscience ought to be a law to himself, and he should not be bound down because chloral hydrate is held by the Privy Council not to be a poison. Chloral was as dreadful a poison as opium, but it acted strangely and capriciously, and paralysed the heart, and the system could not resist it as it could do opium. Death in most cases of chloral poisoning was very sudden.

Mr. Taylor said he was very strict with regard to the sale of any poisons. They were locked in a place by themselves, and he used very great caution when he dispensed them, and so far as he knew, his assistants did the same. He could not use any more precaution than he did.

The Coroner summed up in private, and the jury returned a verdict that "Deceased came to his death through paralysis of the heart, produced by his having inadvertently taken an overdose of chloral to relieve pain." They also appended to their verdict that "they wished steps to be taken by the Coroner for including chloral in the list of poisons in Schedule A of the Pharmacy Act." —The jury, we understand, exonerated Mr. Taylor from all blame.—*Carlisle Journal.*

A Disputed Milk Analysis.

A case of alleged milk adulteration has been heard in the Salford Borough Police Court, in which the defendant put forward a singular plea. A milk dealer was summoned for selling milk adulterated with 11 per cent. of water. Two samples had been taken by the officer from cans in the defendant's cart, and Mr. Carter Bell deposed that these samples had been examined by him: one he found to be comparatively pure and passed it, but the other contained 11 per cent. of water. The standard he had adopted was 9·2 per cent. of solids not fat, and in this case he had found but 8 per cent. On the part of the defendant it was sworn that he had removed the seals from the sealed portions left in his possession in the presence of a witness, and taken the milk to the Town Hall to have it analysed, and that Mr. Bell's own certificate, which was produced, stated that both samples were pure. Mr. Bell was recalled and said that he was positive the two samples left on the 27th February were not of the same quality as those he analysed on the 21st. On his behalf it was requested that the third sample of milk taken by the inspector might be sent to Somerset House to be analysed. Eventually the bench decided that there was a doubt as to the commission of the offence and dismissed the case.

Several other milk cases were heard at the same sitting in which there were convictions, and one in which the analyst's certificate as to adulteration had been confirmed by the chemical department at Somerset House.

Poisonous Coatings for Hams.

At Liverpool on the 28th ult., Henry Thompson, provision merchant and Italian warehouseman, was summoned before Mr. Raffles, for exposing for sale hams which had been "coloured, stained, and powdered" with chromate of lead, so as to render the hams injurious to health.

Inspector Luya proved going to the defendant's shop and purchasing a ham which was wrapped in a cloth covered with red powder. Witness cut the ham in three parts; gave one part to Dr. Brown, one to the defendant, and retained the other.

Dr. Campbell Brown said he received from the inspector the ham. Witness took it out of the canvas and looked to see whether any of the powder with which the canvas seemed to be saturated was upon the ham. There was some of the powder upon the cut surface and the under surface of the ham. He had some of the ham cut up, and always found a small portion of the powder upon the cuts. He analysed the powder which was upon the canvas, and found it was chromate of lead, which is an active poison, and produced colic.—Mr. Raffles: What is the object of putting on the powder? Dr. Brown: I don't know, except it is to make it gaudy.—Mr. Thompson: The hams in question are as I bought them. You will find the same hams in fifty places in Liverpool.

Dr. Brown, in reply to Mr. Raffles, said he did not suppose the powder would always be found upon the ham, but it was liable to be there. It was a very dangerous poison, and a large quantity of it was upon the canvas.

Mr. Raffles (to the defendant): What is the object of putting the powder upon the canvas? Mr. Thompson: I don't know any object except to protect it from flies. The hams are highly recommended, and persons inquire for them.—Mr. Raffles: What do you call them? Mr. Thompson: Sugar-cured American hams. In New York nothing else is sold for home consumption.—Mr. Raffles: Packed like this? Mr. Thompson: Yes.—Dr. Brown said the ham itself was very good.

Dr. Taylor, the deputy medical officer of health, said chromate of lead was a corrosive irritant, and produced inflammation of the bowels. It was equally dangerous as packing the hams in arsenic.

Mr. Raffles said the prosecution would have done better if they had brought a batch of the persons who sold these hams; it seemed like making one person a victim. He questioned whether the case came under the section. The defendant did not sell the article coloured in this way. The covering is not an article of food. It was no doubt a practice that should be stopped, and he thought the prosecution a very proper one, but he could not say that it was an article sold that was mixed, stained, or coloured. The summons was therefore dismissed.—*Liverpool Daily Courier.*

Attempted Suicide with Vermin Killer.

On Saturday week a man was charged before the Hastings magistrates with attempting to commit suicide by taking a portion of a packet of Battle's vermin powder. Evidence was given by Mr. Mackenzie that he had sold a packet of Battle's vermin killer to the prisoner, who said he wanted to poison a dog. The packet was labelled "poison," and witness cautioned him to be very careful with the poison, and to destroy any he might have left. The prisoner was committed for trial.

Review.

On Fermentation. By P. Schutzenberger (Director at the Chemical Laboratory at the Sorbonne). H. S. King and Co. London: 1876.

This work forms the 20th volume of the International Scientific Series, and as might be expected from the pen of the author, it constitutes an excellent digest of all that is known regarding the complicated phenomena of fermentation. Besides being complete in comprehensiveness, it is most readable and is enriched by the incorporation of the well known researches of Schützenberger.

The work before us is divided into two books, the first comprising thirteen chapters and the second, three chapters; there are further given a number of figures chiefly in illustration of the various kinds of ferments, and to show the processes of budding and spore formation.

Regarding fermentation as a particular instance of a biological reaction, manifesting itself as the result of the special force residing in organisms, Schützenberger adopts as nearly as possible the well known theory of Pasteur, and gives to that of Liebig little attention beyond enunciating its main features.

After briefly describing some historical observations in regard to fermentation, the author proceeds to consider more especially alcoholic or spirituous fermentation, and concludes that this is brought about through "a special mechanical action, exercised on the ultimate particles of the compound matter" (sugar), the result of which is that the sugar is split up into alcohol and carbonic dioxide, while glycerine and succinic acid are formed also at the expense of the sugar; besides this the sugar gives up matter to form new ferment. The lactic acid which generally accompanies alcoholic fermentation is considered is proved to be due to the presence of a minute amount of a foreign ferment.

Now Pasteur regards fermentation as essentially "a correlative phenomenon of a vital act, beginning and ending with it," so that wherever there is fermentation, there is organization, development, and multiplication of globules of the ferment itself. Liebig on the other hand neglected the element of life and regarded fermentation as due to a disturbance of equilibrium imparted to the elements of bodies by virtue of an existing change or motion in other bodies. Pasteur and Liebig have at no time in the history of the discussion between them relative to this matter agreed, and the last paper written by the illustrious Liebig was a refutation of some of the later inferences drawn by Pasteur on this subject.
